INDEX

ABBADIE (M. ANTOINE D'), the Variation of Terrestrial Latitudes, 65
Abbe (Prof. Cleveland), Atmospheric Radiation of Heat, and its Importance in Meteorology, 67
Abbe's (Prof.) Improved Spherometer, 472
Abbot (Dr. W. L.), on the Climate of Kilima-Njaro, 160
Abel's (Sir F.) Presidential Address to the Iron and Steel Institute, 111
Aberration, Determination of the Constant of, Prof. G. C. Comstock, 41
Aberration Problems, Dr. Oliver J. Lodge, F.R.S., 497
Abney (Capt., F.R.S.), Star Magnitudes, 41; Transmission of Sunlight through Earth's Atmosphere, ii. Scattering at different Altitudes, 69
Abraham (H.), Electro-magnetic and Electrostatic C.G.S. Units, 168
Absorption, Experimental Proof that the Co-efficient of, is not affected by Density of Illumination, Dr. W. Peddie, 385
Absorption and Filteration of Sewage, R. F. Grantham, 429
Acorn-eating Birds in Michigan, Dr. Morris Gibbs, 495
Acoustics: An Acoustic Method whereby the Depth of Water in a River may be Measured at a Distance, Frederick J. Smith, 246; Musical Sands, C. Carus Wilson, 44; T. S. Hall, 279; Influence of Acoustic Clouds, David Cunningham, 430
Acquired Characters, the Bearing of Pathology upon the Doctrine of the Transmission of, Henry J. Tylden, 302
Acquired Characters, the Transmission of, through Heredity, Prof. C. V. Riley, 504
Active Lunar Volcanoes? Prof. Pickering, 134
Adams (Prof.), Proposed Memorial to, in Westminster Abbey, 208
Addenbrooke (G. L.), the Use and Application of Aluminium, 63
Aden Survey, Completion of, 212
Aeronautics: Modern Aërial Navigation, Capt. J. D. Fullerton, 63; Flying Machine Work, L. Hargrave, 556
Africa: Tanganyika, Eleven Years in Central Africa, Edward Coode Hore, 6; Emin Pasha's Return Expedition to the Equatorial Lakes, Dr. Stuhlmann, 110, 302; Lieut. Mizon's Explorations, 110; Two Pillars erected by Diogo Cão, the First Portuguese Explorer, on West Coast of Africa, brought back to Lisbon, 111; the Pigmies of Africa, Dr. H. Schlichter, 135; Immunity of the African Negro from Yellow Fever, Dr. C. Creighton, 200, 222; Meteorological Observatories at Banana, Dr. Etienne, 255; the Uganda Question, 280; Dr. O. Baumann's Survey of Road to Victoria Nyanza, 280; Discovery of a New Great Lake (Lake Eiassi), 280; Diamond Robbery from a South African Museum, 332; Geodetic Survey of South Africa, 362; African Travels, 407; Industrial Resources of Nyasaland, John Buchanan, 407; African Meteorology, 407; the Mombasa-Victoria-Nyanza Survey, 453; Railways in Tropical Africa and Native Passengers, 453; Founding of Robinson Commemoration Association for Study of Hausa Language and People, 572; Camels in German South-West Africa, 598; the Dra Dwarfs, E. G. Dönnenberg, 616; Mr. Joseph Thomson's Journey to the Lake Bangweola Region, 620
Agriculture: Egyptian Agriculture, Prof. Robert Wallace, 15; Report on the Relations of Fruit Production in New South Wales to the English Market, F. W. Ward, 39; Agriculture in United States; Official Denial of the reported intention of the Government to introduce Mongoose to exterminate troublesome Rodents in the West, 39; Live Stock, Prof. Wrightson, 76; Appearance of the Diamond-back Moth in Yorkshire and Northumberland, 108; Soils and Manures, John M. H. Munro, 125; A New Method of Rabbit Destruction in New South Wales, 161; Perfume-flower Farming in New South Wales, 161; The Carob-bean Tree in New South Wales, F. Turner, 210; Royal Agricultural Society's Journal, 262; Vermin of the Farm, J. E. Harting, 262; Yorkshire College, Leeds: The County Lectures to Farmers, 300; Coffee, Cacao and Rubber Cultivation in Ceylon, J. Ferguson, 300; Utilization of Stripped Autumn Plants as Green Manure, P. P. Dehérain, 364; The Vole Plague in the Border Districts, 395; Copper Sulphate Spray as Fungicide, 422; Agricultural Education at University College of North Wales, Bangor, 474; the Manufacture of Iron in its Relations with Agriculture, Sir Lowthian Bell, 525; Contagious Foot Rot in Sheep, Prof. G. T. Brown, 560; A Text-book of Agricultural Entomology, Eleanor A. Ormerod, 561; Allotments and Small Holdings, Sir J. B. Lawes and Dr. Gilbert, 602; Dr. Leather's Method of Detecting and Estimating Castor-oil Seeds in Cattle Foods, 602; The Improvement of the Potato in Australia, 617; Birds versus Insects in Malta, 618
Aikman (C. M.) Farmyard Manure, 100
Ainos of Japan, the, Mrs. Isabella Bishop, 119; R. Hitchcock, 421; Arrow Poisons used by, Romyn Hitchcock, 475
Air, Radiation of Atmospheric, C. C. Hutchins, 67
Air Leyden, A New Form of, Lord Kelvin, P.R.S., 212
Aitken (John, F.R.S.), on Some Phenomena connected with Cloudy Condensation, 90
Akroyd (William), the Law of Colour in relation to Chemical Constitution, 23
Alaska, Acclimatization of Reindeer in, by Dr. Sheldon Jackson, 109
Alaskan Grave, Ancient Chinese Coins discovered in an, Lieut. Dix Bolles, 574
Albino Animals in Japan, Importance attached to, Herr J. L. Janson, 493
Albumen in Plants, the Active, O. Loew, 491
Alcock (Dr. A.), the Marine Survey of India, 549; The Red Ocypode Crab, 549; the Little Estuarine Crab Gelasimus, 574
Aldabra Island, Seychelles, the Gigantic Land Tortoise of, Riseley Griffiths, 398
Algeria, Miocene Formations of Western, Jules Welsch, 628
Alheilig (M.) Recette, Conservation et Travail des Bois, 246
Alloys, the Microscopic Structure of, Behrens, 72
Alloys, on Certain Ternary, Aluminium, &c., C. R. A. Wright, F.R.S., 188
Alloys of Iron and Chromium, the, R. A. Hadfield, 526
Alluaud's (Charles), Researches in the Island of Mahé (Seychelles), 230
Alpine Glaciers, the Present Extension of; the Glacier des Boisons, 370
Alpine Glaciers, the Periodic Variations of, F. A. Forel, 386
Alpine Trias, Brachiopods of the, A. Bittner, F. A. Bather, 25
Alterations of Personality, Alfred Binet, 219
Alternative Hypothesis, Natural Selection and, F. E. Beddard, F.R.S., Edward B. Poulton, F.R.S., 533

Aluminium, the Uses and Applications of, G. L. Addenbrooke, 63
Aluminium, Specific Heat and Latent Heat of Fusion of, J. Pionchon, 312
Amagat (E. H.), Elements of Critical Point of Carbonic Acid, 96
Amber Mines of Upper Burma, Dr. Noetling, 549
Ambronn (Dr. L.), the Trapezium in the Orion Nebula, 334
America: Discovery of Australian-like Mammals in South America, R. Lydekker, 11; Palæonictis in the American Lower Eocene, Henry F. Osborn, 30; Revision of the Species of Rumex occurring North of Mexico, W. Trelease, 40; American Journal of Science, 67, 310, 627; American Journal of Mathematics, 68, 627; the Development of American Armour-plate, F. L. Garrison, 86; Science in America, the Walker Prize awarded to Prof. J. D. Dana, 158; Alleged Discovery by Cyrus Thomas of the Key to the Central American Inscriptions, 160; Projected Marine Biological Laboratory in Jamaica in commemoration of Quater-Centenary of Discovery of America, 176; Discovery of America to be Celebrated in Hamburg, October 11–12, 230; American Meteorological Journal, 235, 435, 483, 555; Locusts in America, C. V. Riley, 256; the Tertiary Rhynchophora of North America, S. H. Scudder, 256; Proposed American Psychological Association, 419; American Association for the Advancement of Science, President's Address, 408; Rochester Meeting, 453; Section A, some Problems in the Old Astronomy, J. R. Eastman, 424; Annual Convention of American Association of State Weather Services, 493; Science in the United States, W. Kent, 494; the First Chart of America, Juan de la Cosa's, 453
Amsterdam Royal Academy of Sciences, 72, 216, 263, 628
Analytical Statics, a Treatise on, Edward J. Routh, F.R.S., Prof. A. G. Greenhill, F.R.S., 145
Anatomy, Quain's Elements of, 6
Anatomy Museum at Pennsylvania University, Endowment by General Wister of, 38
Anatomy, Physiology, Morphology, and Development of the Blow-fly (*Calliphora erythrocephala*), B. Thompson Lowne, 267
Anchor Ring, the Potential of an, F. W. Dyson, 92
Anderson (Ernest), Some Victorian Lepidoptera, 595
Anderson (Dr. W., F.R.S.), Inaugural Address as President of Institution of Mechanical Engineers, 42
Andes, Collections from the, Edward Whymper, H. J. Elwes, 147
Andrew (Captain Edgar H.), Ice in the South Atlantic, 173
Andrussoff (Dr.), Results of the Recent Russian Investigations on the Black Sea, 408
Anemometer, Timchenco's, Prof. Klossovsky, 594
Angell (John), Elements of Magnetism and Electricity, 610
Animal Coloration: an Account of the Principal Facts and Theories Relating to the Colours and Markings of Animals, F. E. Beddard, F.R.S., Edward B. Poulton, F.R.S., 533
Animal Heat and Physiological Calorimetry, Prof. Rosenthal, 403
Animal Intelligence, the Limits of, Edward T. Dixon, 392; C. Lloyd Morgan, 417; Dr. St. George Mivart, F.R.S., 466
Animal Life Past and Present, Phases of, R. Lydekker, 74
Animals, Land, the Origin of; a Biological Research, W. J. Sollas, 271
Animals in Captivity in Lower Bengal, a Handbook on the Management of, Ram Bramha Sányál, 314
Annelid, the Protective Device of an, A. T. Watson, 7
Annuaire Géologique Universel, L', 109
Anniversary Meeting of the Royal Geographical Society, President's Address, 87
Ant-bear in Cape Colony, the Extermination of the, A. C. Macdonald, 522
Antarctic Expedition, Abandonment of the Proposed, 230
Antarctic Whaling Expedition; Sailing of the Dundee, 477
Ants in Ceylon, W. F. Liesching, 15
Ants and Saccharine, H. Devaux, 573
Ants, Habits of Parasol, J. E. Tanner, 595
Anthropology: the Religious and Social Ideas of the Chinese, as illustrated in the Ideographic Characters of the Language, Prof. R. K. Douglas, 23; Anthropological Institute, 23, 119, 238; Anthropology as a branch of University Education, Dr. D. G. Brinton, 39; the Ainos of Japan, Isabella Bishop, 119; R. Hitchcock, 421, 475; the British Association's Notes and Queries on Anthropology, 160; the Todas, 160; the Acceleration of Mortality in France, M. Delauney, 168; the True Basis of Anthropology, Horatio Hale, 206; Immunity of the African Negro from Yellow Fever, Dr. C. Creighton, 200, 222; an Ethnological Enquiry into the Basis of our Musical System, Dr. Wallaschek, 238; Easter Island, W. J. Thomson, 258; Opening Address in Section H, by Prof. Alexander Macalister, F.R.S., at the British Association, 378; on the Organization of Local Anthropological Research, E. W. Brabrook, 432; on the Discovery of the Common Occurrence of Palæolithic Weapons in Scotland, Rev. Frederick Smith, 432; Weapons and Articles of Clothing used by the Toba Indians of the "Gran Chaco," J. Graham Kerr, 432; "Pre-Palæolithic" Flints, J. Montgomerie Bell, 432; on the Present Inhabitants of Mashonaland and their Origin, J. Theodore Bent, 432; the Value of Art in Ethnology, Prof. A. C. Haddon, 432; on the Similarity of certain Ancient Necropoleis in the Pyrenees and in North Britain, Dr. J. S. Phené, 432: Anthropometric Identification, Dr. Manouvrier, 432; Criminal Anthropology, Dr. T. S. Clouston, 432, Dr. Benedikt, 433; Coiffure of a Kanaka Labourer, Sir William Turner, 433; Prehensile Power of Infants, Dr. Louis Robinson, 433; on the Contemporaneity of the Maori and the Moa, H. O. Forbes, 433; Human Osteometry, Dr. Garson, Sir William Turner, 433; Observations as to the Physical Deviations from the Normal as seen among 50,000 Children, Dr. Francis Warner, 433; on some Facial Characters of the Ancient Egyptians, Prof. A. Macalister, 433; Ancient Skeletons from Medum, Egypt, Dr. Garson, 433; German Anthropological Congress, 420; Copper Implements and Ornaments in Ohio Mounds, Prof. F. W. Putnam, 455; the Ulu or Woman's Knife of the Eskimo, O. T. Mason, 550; the Dra Dwarfs, E. G. Dönnenberg, 616
Anthropometric Identification, Dr. Manouvrier, 432
Anticyclone over British Islands and Atlantic, 38
Anti-Friction Material for Bearings used without Lubrication, Killingworth Hedges, 430
Aphanapteryx and other Remains in the Chatham Islands, Henry O. Forbes, 252
Apiculture: Amount of Honey needed to enable Bees to secrete one pound of Wax, A. J. Cook, 255
Aplysiidæ, Physiology of the Glands of Bohadsch in the, G. F. Mazzarelli, 163
Apodidæ, the: a Morphological Study, H. M. Bernard, Prof. E. Ray Lankester, F.R.S., 267
Apodidæ, the: a Reply, Henry M. Bernard, 366
Archæan History, Subdivisions in, Prof. James D. Dana, 152
Archæology: the Tell el-Amarna Tablets in the British Museum, 49; the Coming Moscow International Congress of Prehistoric Archæology, 108; Proposed Testimonial to Signor G. Fiorelli on his Retirement, 176; Discovery of Buddhist Antiquities at Bhatuprolu, A. Rea, 178; Herr K. Flegel's Discoveries in Kalymnos, 521; the Recent Discovery of an Ancient Lake-Village in Somersetshire, Dr. A. Munro, 617
Archipelago, Eastern, the Deep-Sea Deposits of the, P. W. Bassett-Smith, 69
Archoplasmic Body, on the Relationships and Rôle of the, during Mitosis in the Larval Salamander, J. E. S. Moore, 404
Arctic Expedition, the *Manche*, 397
Arctic Exploration: the Relief of the Peary Expedition, 476
Arctic Regions; Prof. Pouchet's Visit to Jan Mayen and Spitzbergen, 453
Arenig Age, on the Radiolarian Chert of, Messrs. Peach and Horne, 428
Arithmetic, Mental, G. Daehne, 247
Arithmetic for Beginners, Key to, J. and E. J. Brooksmith, 441
Arithmetical Chemistry, C. J. Woodward, 610
Arloing (M.), the Phylacogenic Substance in Ordinary Liquid Cultivations of *Bacillus anthracis*, 240
Armour-plate, American, the Development of, F. L. Garrison, 86
Armstrong (Prof. H. E., F.R.S.), the International Conference on Chemical Nomenclature, 56; the Origin of Colour, ii., the Constitution of Coloured Nitro-compounds; iii. Colour as an Evidence of Isodynamic Change, 142; British Association Procedure, 291

Arrow Poisons used by the Ainos of Japan, Romyn Hitchcock, 475

Arsonval (A. d'), Physiological Effects of Alternating Currents with Sinusoidal Variations, 240

Art: the Black and White Handbook to the Academy and New Gallery Pictures, 84

Art in Ethnology, the Value of, Prof. A. C. Haddon, 432

Aryan Race, Omalius d'Halloy the author of the Theory of the European Origin of the, Dr. Brinton, 278

Ascidian, a Functional Hermaphrodite, Prof. W. A. Herdman, F.R.S., 561

Ascidians, on the Geographical Distribution of, Prof. W. A. Herdman, F.R.S., 405

Asia, Central, Brick Manufacture in, Edouard Blanc, 604

Assmann's (Dr. R.) Aspiration Apparatus, 361; Treatment of Persons Struck by Lightning, 521

Asteroids, Numeration of, 372

Asters and Perennial Sunflowers, J. G. Baker, 14

Aston (Miss), Atomic Weight of Boron, 403

Astronomy: Astronomical Column, 16, 41, 64, 86, 110, 134, 161, 179, 211, 229, 257, 279, 301, 334, 362, 371, 400, 423, 452, 476, 496, 524, 551, 575, 597, 619; Prof. Tacchini on Sun-spots, 16; Photographs of Sun-spots, 258; the Influence of Sun-spots on Terrestrial Magnetic Conditions, 278; Atmospheric Depressions and their Analogy with the Movements of Sun-spots, M. Camille Flammarion, 280; Sun-spot Observations at the Lyons Observatory, E. Marchand, 340; Eclipse of the Moon, May 11, 17; Comet Swift (March 6), 1892, 17, 65, 87, 230, 258, 423, 453; Spectrum of Swift's Comet (*a* 1892) W. W. Campbell, Prof. Konkoly, 17; Nova Aurigae, Prof. Konkoly, 17, "L'Astronomie," 161, Rev. A. Freeman, 453, H. F. Newall, 489, Herr Belopolsky, 552, 576, Dr. J. Holetschek, 576; Nebular Spectrum of, R. Copeland, 464; Spectrum of, Herr E. von Gothard, 620; Increase of, 400; Photographic Magnitudes of, J. M. Schaeberle, 423; Brightness of, 476, 496; a New Variable, T. E. Espin, 17; a New Variable Star, Prof. Schaeberle, 620; New Variable Stars, Prof. Pickering, 334; Variable Star T Cassiopeiæ, Cuthbert E. Peek, 443; Aurora, Dr. M. A. Veeder, 29, H. Geelmuyden, 55; Photographic and Visual Magnitudes of Stars, Prof. J. C. Kapteyn, 41; Photographs of the Lyra Ring Nebula, Prof. Denza, 41; Determination of the Constant of Aberration, Prof. G. C. Comstock, 41; Star Magnitudes, Captain Abney, 41; Captain Weir's Azimuth Diagram, 44; Latitude Observations at Waikiki, Mr. Preston, 64; Motion in the Line of Sight, W. W. Campbell, 64; Declinations of Stars for Reduction of Variations in Latitude, 65; Comet 1892, Denning (March 18), 65; Lunar Eclipse, May 11, 1892, 64, 372; Observations of the Moon, 179; Bright Streaks on the Full Moon, Prof. Pickering, 476; the Variation of Terrestrial Latitudes, M. Antoine d'Abbadie, 65; the Radiants of the Andromedides, Th. Bredikhine, 68; the Libration of Hyperion, H. Struve, 68; Distribution of Stars in Space, Kapteyn, 72; Paris Observatory Report, 86; Stars with Remarkable Spectra, 86; Light Variations of γ Cygni, Prof. Dunér, 87, 134, Mr. Yendell, 134; Nebulæ, Mr. Burnham, 87; Catalogue of Nebulæ, 135; Variable Nebulæ, E. E. Barnard, 211; Winnecke's Periodic Comet, 1892, 110; Saturn's Rings, M. Bigourdan, 110, Rev. A. Freeman, 150; Stone Circles, the Sun and the Stars, A. L. Lewis, 127; Active Lunar Volcanoes, Prof. Pickering, 134; Photographic Measures of the Pleiades, 161; the Planet Mars, 162; Colours on the Surface of Mars, Prof. Pickering, 179; Opposition of Mars, 258, 400, J. Norman Lockyer, F.R.S., 443; Observations of Mars, M. Perrotin, 482; Measures of the Diameter of Mars, Camille Flammarion, 460; Earth-fractures and Mars "Canals," Prof. G. A. Lebour, 611; Death of Narasinga Row, 176; a New Planisphere, 177; a Planet beyond Neptune, Prof. Forbes, Mr. Roberts, 179; Total Solar Eclipse, April 15-16, 1893, 201; Variation of Latitude, Mr. Chandler, 211; Comparative Spectra of High and Low Sun, 211; Coronoidal Discharges, M. I. Pupin, 211; the Red Spot on Jupiter, J. J. Landerer, 229, W. F. Denning, 391; Position of Jupiter, 453; Discovery of a New Satellite to Jupiter, 476, 592; Discovery of a Fifth Satellite to Jupiter, W. F. Denning, 492; Jupiter's Fifth Satellite, Prof. Barnard, 620; Jupiter and his System, Miss E. M. Clarke, 620; a Mean Time Sun-dial, Major-General Oliver, 230; Stars' Proper Motions, J. G. Porter, 230; Determination of Angle of Polarization of Venus, J. J. Landerer, 240; Lunar Photography, Dr. L. Weinek, Prof. Holden, 257; Remarkable Prominences, M. Trouvelot, 258; Influence of Place of External Thermometer in Observations of Zenith Distances, M. Perigaud, 263; a New Nebulous Star, E. E. Barnard, 279; Yale College Observatory Report, Mr. Brown, Dr. Elkin, 280; Madras Observatory, 301; Oxford University Observatory, 301; Natal Observatory, 362; In Starry Realms, Sir Robt. S. Ball, F.R.S., 315; Solar Observations at the R. Osservatorio del Collegio, Romano, Prof. Tacchini, 334; a Remarkable Prominence, J. Fényi, 334; the Trapezium in the Orion Nebula, Dr. L. Ambronn, 334; New Results with Regard to Hydrogen obtained by Spectroscopic Study of Sun, M. Deslandres, 340; Geodetic Survey of South Africa, 362; the Perseids, W. F. Denning, 371, J. Edmund Clark, 442; Himmel und Erde, 371; Astronomy at the Columbian Exposition, 372; Numeration of Asteroids, 372; Thermal Absorption in the Solar Atmosphere, E. B. Frost, 400; Hydrogen Spectrum in the Solar Atmosphere, M. Deslandres, 401; Refraction in Micrometric and Photographic Measures, Dr. S. C. Chandler, 401; Comparison Stars of the Planet Victoria, Dr. Gill, 423; International Time, Major the Hon. E. Noel, 423; Some Problems in the Old Astronomy, J. R. Eastman, 424; the Staff at the Lick Observatory, 452; the Observations of Klinkerfues Reduced, Prof. William Schur, 452; Photographs of Solar Phenomena, Prof. G. E. Hale, 452; A Meteorite, H. L. Preston, 452; Mounting of Objectives, Prof. Hale, 452; Discovery of a New Comet by Mr. Brooks, 453; Observations of New Planet M. Wolf, G. Bigourdan, 460; the Planet Venus, E. L. Trouvelot, 468; Variation of Latitude, Dr. Chandler, 476; the Variation of Latitude at Pulkova, B. Wanach, S. Kostinsky, 524; Double Star Observations, Prof. Asaph Hall, 524; New Observatories, 476; Solar Observations at Rome, Prof. Tacchini, 476, 524; Proposed School of Practical Astronomy, H. C. Russell, 496; Double Star Measures, S. W. Burnham, 496; Comet Brooks (1882, August 27), 496; Comets of Brorsen (1846 VII.) and Brooks (1892 "*d*"), W. F. Denning, 514; Comet Brooks (August 27, 1892), F. Ristenpert, 551; Comet II. 1892 (Denning, March 18), 541, 551; Astronomische Nachrichten, 552; Appeal by Harvard Observatory for Donation to construct Refracting Telescope, E. C. Pickering, 548; the Present Comets, T. W. Backhouse, 561; Total Eclipse of the Sun, 1893, John King, William M. Martin, 561; Luminous Night Clouds, W. Foerster and O. Jesse, 575; Minor Planets, 576; Report of Mr. Tebbutt's Observatory, 576; Photographic Chart of the Heavens, H. C. Russell, 576; Dr. Rambaut, the New Royal Astronomer for Ireland, 615; A New Comet discovered by Prof. Barnard, 597; our Sun's History, Lord Kelvin, 597; Silvering Glass Mirrors, Mr. Common, 597; Himmel und Erde, 598; Researches in Stellar Parallax by the aid of Photography, Prof. Chas. Pritchard, F.R.S., 612; Comet Barnard (October 12), 619; Discovery of Three New Planets by Photography, 619; Rutherfurd Measures of Stars about β Cygni, Harold Jacoby, 619

Atlantic, Icebergs in the, 160

Atlantic, North, Pilot Chart of, for April, 38

Atlantic, North, the Crinoids and Echinoids of the, Dr. Danielssen, 333

Atlantic, South, Ice in the, Robert H. Scott, F.R.S., 173; Capt. Edgar H. Andrew, 173

Atlas of Clinical Medicine, Dr. Byrom Bramwell, 389

Atomic Weight of Boron, Prof. Ramsay and Miss Aston, 403

Atomic Weight of Oxygen, Robert Lehfeldt, 151

Atmosphere, the General Circulation of the, J. Carrick Moore, F.R.S., 7

Atmospheric Depressions and their Analogy with the Movements of Sun-Spots, M. Camille Flammarion, 280; F. Howard Collins, 489

Auriga, the Late New Star in, 161

Aurora, Dr. M. A. Veeder, 29, H. Geelmuyden, 55, James Porter, 151; Remarkable Aurora Borealis over Moscow, 39; Aurora in Canada, 361; Aurora Borealis, Warington Stock, 79, A. Butcher, 368, Rev. Edmund McClure, 368, J. Lloyd Boyward, 368, Henry Harries, 391; Aurora Australis, William White, 368, H. S. Dove and G. W. Easton, 368

Austen (Prof. Roberts), Effect of Small Quantities of Foreign Matter on the Properties of Metals, 402
Australia: Discovery of Australian-like Mammals in South America, R. Lydekker, 11; the Spread of Foxes in Australia, 15; F. W. Ward's Report on the relations of Fruit Production in New South Wales to the English Market, 39; Photographs of Coral Reefs and Marine Fauna of Great Barrier District of, W. Saville-Kent, 45; Excursion of Victoria Field Naturalists' Club to the Grampians, 63; the Sanderling in Australasia, Prof. Alfred Newton, F.R.S., 177; Australian Crustacea: a Tube-dwelling Amphipod (*Cerapus flindersi*) from Port Jackson, Charles Chilton, 178; Australian Mud Springs, Prof. Edgeworth David, 256; Fruit Culture in Australia, 494; the Great Barrier Reef of Australia, W. Saville-Kent, 523; the Improvement of the Potato in Australia, 617
Ayrton (Prof. W. E., F.R.S.), Workshop Ballistic and other shielded Galvanometers, 214
Azoimide, N_3H, Inorganic Synthesis of, A. E. Tutton, 286

Babes (V.), Carceag, an Enzootic Disease of the Sheep in Roumania, 436
Backhouse (T. W.), Numbering the Hours of the Day, 392; the Present Comets, 561
Bacteriology: Structure of Bacterial Cells, W. K. Wahrlich, 39; a New Bacterium (*Nevskia ramosa*), A. Famintzin, 68; Micro-organisms in their Relation to Chemical Change, Prof. Percy F. Frankland, F.R.S., 135; the Nitric Organisms, R. Warington, F.R.S., 151; Prof. Percy F. Frankland, F.R.S., 200; Bacteriologisches Practicum zur Einführung in die practischwichtigen bacteriologischen Untersuchungsmethoden für Aerzte, Apotheker, Studirende, Dr. W. Migula, Mrs. Grace C. BRITISH ASSOCIATION: Meeting at Edinburgh, 298, 316, 341; F. Grant Ogilvie, 270; British Association Procedure, Henry Armstrong, 291; Inaugural Address at Edinburgh by Sir Archibald Geikie, LL.D., For.Sec.R.S., 317; British Association Committee on Electrical Standards, Prof. Oliver J. Lodge, F.R.S., 334, 368

Section A (*Mathematics and Physics*)—Opening Address by Prof. Arthur Schuster, F.R.S., President of the Section, 323; Discussion on a National Physical Laboratory, Prof. Oliver J. Lodge, F.R.S., 382; R. T. Glazebrook, F.R.S., 383; Prof. von Helmholz, F.R.S., 383; Lord Kelvin, F.R.S., 383; Prof. Rücker, F.R.S., 383; Prof. Fitzgerald, F.R.S., 383; Discussion on Nomenclature of Units, 383; Report on Underground Temperature, 383; Report on the Discharge of Electricity from Points, 383; Report on Electrical Standards, 383; Wire Standards of Electric Resistance, Dr. Lindeck, 383; Dr. Kahle on the Clark Cell, 383; Preliminary Account of Oceanic Circulation based on the *Challenger* Observations by Dr. A. Buchan, 383; Physical Condition of the Waters of the English Channel, H. V. Dickson, 384; on Primary and Secondary Cells in which the Electrolyte is a Gas, Prof. Schuster, F.R.S., 384; on Leaky Magnetic Circuits, Dr. du Bois, 384; Experiments on the Electric Resistance of Metallic Powders, Dr. Dawson Turner, 384; on the Stability of Periodic Motions, Lord Kelvin, F.R.S., 384; on the Specific Conductivity of Thin Films, Profs. Reinold and Rücker, 384; a Contribution to the Theory of the Perfect Influence Machines, J. Gray, 384; Experiments with a Ruhmkorff Coil, Magnus Maclean and A. Galt, 384; the Application of Interference Methods to Spectroscopic Measurement, Prof. A. Michelson, 385; on a Periodic Effect which the Size of Bubbles has on their Speed of Ascent in Vertical Tubes containing Liquid, Dr. F. T. Trouton, 385; on a Method of Determining Thermal Conductivities, C. H. Lees, 385; a Magnetic Curve Tracer, Prof. Ewing, 385; on a Magnetic Balance and its Practical Use, Prof. du Bois, 385; on Earth Current Storms in 1892, W. H. Preece, 385; on the Dielectric of Condensers, W. H. Preece, 385; on Polarizing Gratings, Prof. du Bois, 385; the Volume Effects of Magnetism, Dr. C. G. Knott, 385; an Estimate of the Rate of Propagation of Magnetization in Iron, Prof. Fitzgerald, 385; Experimental Proof that the Co-efficient of Absorption is not Affected by Density of Illumination, Dr. W. Peddie, 385; on Dispersion in Double Refraction due to Electric Stress, Dr. John Kerr, 385; on a Delicate Calorimeter, J. A. Harker and P. J. Hartog, 385; on Graphic Solutions of Dynamical Problems, Lord Kelvin, 385; Reduction of Every Problem of Two Freedoms in Conservative Dynamics to the Drawing of Geodetic Lines on a Surface of given Specific Curvature, Lord Kelvin, 386

Section B (*Chemistry*)—Opening Address by Prof. Herbert McLeod, F.R.S., President of the Section, 327; Prof. Crum Brown on Electrolytic Synthesis, 401; Prof. Ramsay on the Impurities in Chloroform, 401; Prof. Lewes on the Luminosity of Hydrocarbon Flames, 401; Experiments on Flame, Prof. Smithells, 402; the Reaction of Hydrogen with Mixtures of Hydrogen and Chlorine, Dr. J. A. Harker, 402; Prof. Clowes on a New Safety Lamp, 402; Prof. Roberts Austen on the Effect of Small Quantities of Foreign Matter on the Properties of Metals, 402; Dr. Gladstone on the Molecular Refraction and Dispersion of Metallic Carbonyls and of Indium Gallium and Sulphur, 402; Dr. G. H. Bailey on Impurities of Town Air, 402; Prof. Ramsay and Miss Aston on the Atomic Weight of Boron, 403

Section C (*Geology*)—Opening Address by Prof. C. Lapworth,

F.R.S., President of the Section, 372; Messrs. Peach and Horne on the Radiolarian Chert of Arenig Age, 428; Palæozoic Rocks, Prof. Sollas, Prof. Bonney, 428; Glacial Papers, Dr. Crosskey, Mr. Lomas, Mr. Bell, Messrs. Peach and Horne, 428; Palæontological Papers, E. T. Newton, M. Laurie, 428; Petrological Papers, Mr. Ussher, Mr. Goodchild, Mr. Harker, Mr. Teall, Mr. Somervail, 428; Landslips in the South Tyrol, Miss Ogilvie, 428
Section D (*Biology*)—Opening Address by Prof. William Rutherford, F.R.S., President of the Section, 342; Prof. Waymouth Reid on Vital Absorption, 403; Prof. Rosenthal on Animal Heat and Physiological Calorimetry, 403; Dr. Lockhart Gillespie on Proteid-hydrochlorides, 403; Dr. E. W. Carlier on the Hibernating Gland of the Hedgehog, 403; Dr. G. Mann on the Functions, Staining and Structures of Nuclei, 403; Dr. Henry C. McCook on the Social Habits of Spiders, 403; Prof. A. Crum Brown on a Use of the External Ear, 404; Prof. Lloyd Morgan, the Method of Comparative Psychology, 404; J. E. S. Moore on the Relationships and Rôle of the Archoplasmic Body during Mitosis in the Larval Salamander, 404; Dr. G. Mann on the Origin of Sex, 404; Dr. J. Beard on Larvæ and their Relations to Adult Forms, 404; Method of Recording Curves of Muscular Contraction, Prof. McKendrick, 404; Prof. G. Fritsch on the Origin of the Electric Nerves in the *Torpedo*, *Gymnotus*, *Mormyrus* and *Malapterurus*, 404; Dr. J. Musgrove, the Blood-vessels and Lymphatics of the Retina, 404; H. O. Forbes, Sub-fossil Bones of Extinct Birds of New Zealand and the Chatham Islands, 404; Dr. J. Clark on the Natural Relations between Temperature and Protoplasmic Movements, 404; Dr. J. Clark, Experimental Observations on the Functions of the Nucleus in the Vegetable Cell, 404; Dr. Francis Warner, Co-ordination of Cellular Growth and Action by Physical Forces, 404; M. Louis Olivier, La Canalisation des Cellules et la continuité de la Matière Vivante chez les Végétaux et les Animaux, 404; Dr. John H. Wilson, some Albucas and their Hybrids, 404; Prof. McIntosh, F.R.S., a Sketch of the Scotch Fisheries, chiefly in their Scientific Aspects, during the Decade 1882-92, 404; Prof. Ewart on our Sea Fisheries, 404; E. W. L. Holt on the Destruction of Immature Fish, 404; Dr. W. Ramsay Smith, the Food of Fishes, 405; A. P. Swan, the Effect of Sea Water on the Vitality of the Salmon Fungus, 405; Prof. E. G. Prince on the Formation of Argenteous Matter in the Integument of Teleosteans, 405; Prof. E. E. Murray, Comparison of the Marine Floras of the Warm Atlantic and Indian Ocean, 405; Mr. Harold Wager on the Structure of *Cystopus candidus*, 405; Prof. G. Gilson on the Affinity of Nuclein for Iron and other Substances, 405; Dr. Arthur Robinson's Observations on the Development of the Posterior Cranial and Anterior Spinal Nerves in Mammals, 405; Prof. W. A. Herdman, F.R.S., on the Geographical Distribution of Ascidians, and on the Presence of Atrial Tentacles in various Genera of Tunicata, with a Suggestion as to their Function, 405; Dr. J. Symington on the Cerebral Commissures in the Marsupialia and Monotremata, 405; Prof. J. Playfair McMurrich, the Early Development of the Isopods, 486; Prof. G. B. Howes and J. Harrison on the Skeleton and Teeth of the Australian Dugong, 406; Dr. H. G. McCook, Can Spiders Prognosticate Weather Changes? 406; Observations on Secondary Tissues in Monocotyledons, Dr. Scott and Mr. Brebner, 554; on the Simplest Form of Moss, Prof. Goebel, 554; on the Cause of Physiological Action at a Distance, Prof. L. Errera, 555; Notes on the Morphology of the Spore-bearing Members in the Vascular Cryptogams, Prof. F. O. Bower, 555; on the Arrangement of Buds in Lemna Minor, Miss Nina F. Layard, 555; on Tubercles on the Thallus of *Cystoclonium purpurascens*, Prof. F. Schmitz, 555; *Calamostachys Binneyana*, Schimp, T. Hick, 555; Myeloxylon from the Millstone Grit and Coal Measures, A. C. Seward, 555
Section E (*Geography*)—Opening Address by Prof. James Geikie, F.R.S., President of the Section, 348; the First Ascent of Oraefa Jökull, F. W. W. Howell, 406; Dr. J. Burgess on Place Names, 406; Effect of Rainfall in Formosa, John Thomson, 406; Lesser Tibet, Mrs. Bishop, 406; the North Atlantic, the Prince of Monaco, 406; Detailed Oceanography and Meteorology, 406; the Desert of Atacama, Mrs. Lilly Grove, 406; Photography and Surveying, Colonel Tanner, 407; Determination of Longitude by Photography, Dr. H. Schlichter, 407; African Travels, 407; Industrial Resources of Nyasaland, John Buchanan, 407; African Meteorology, 407; Prof. Penck's Proposed New Map of the Globe, 407; Recent Travels, Walker Harris, 408; H. O. Forbes's Visit to the Chatham Islands, 408; Sub-section on Chemical Oceanography, J. Y. Buchanan, 408; Prof. Pettersson on the Hydrography of the Kattegat and Baltic, 408; Results of the Recent Investigations on the Black Sea, Dr. Andrussoff, Russian 408
Section G (*Mechanical Science*)—Opening Address by W. Cawthorne Unwin, F.R.S., President of the Section, 355; Electrical Lighting of Edinburgh, Prof. George Forbes, 429; Disposal of Town Refuse, Prof. George Forbes, 429; the Refuse-destructor Question, G. Watson, 429; Absorption and Filteration of Sewage, R. F. Grantham, 429; Shield Tunneling in Loose Ground, G. F. Deacon, 429; Proposed Ship Canal between the Forth and the Clyde, D. A. Stevenson, 429; Mechanical System for the Distribution of Parcels, D. Cunningham, 429; Electric Locomotives, Alexander Siemens, 429; a Tide-Motor, F. Purdon and H. E. Walters, 429; Marine Machinery at Glasgow, 430; Necessity for Connection between Stack Pipes and Earth, W. H. Preece, F.R.S., 430; Power Transmission by Alternating Current, Gisbert Kapp, 430; New Design of Electric Locomotive, E. H. Woods, 430; Ingenious Coin-counting Machine in the Royal Mint, Lieut. W. B. Basset, 430; Anti-Friction Material for Bearings used without Lubrication, Killingworth Hedges, 430; Petroleum Engines for Fog Signalling, D. A. Stevenson, 430; Influence of Acoustic Clouds, David Cunningham, 430; Sound-carrying Power of Water, A. R. Sennett, 430; on the Progress of the Dioptric Lens as used in Lighthouse Illumination, C. A. Stevenson, 431; Smoke Prevention, A. R. Sennett, 431; Col. E. Dulier, 431; Investigation of the Phenomena which accompany the Burning of Carbon and Phosphorus in Oxygen, H. Brereton Baker, 431; Fire Extinction on board Ship, H. C. Carver, 432
Section H (*Anthropology*)—Opening Address by Alexander Macalister, F.R.S., President of the Section, 378; E. W. Brabook on the Organization of Local Anthropological Research, 432; Rev. Frederick Smith on the Discovery of the Common Occurrence of Palæolithic Weapons in Scotland, 432; J. Graham Kerr, Weapons and Articles of Clothing used by the Toba Indians of the "Gran Chaco," 432; J. Montgomerie Bell, "Pre-palæolithic" Flints, 432; J. Theodore Bent on the Present Inhabitants of Mashonaland and their Origin, 432; Prof. A. C. Haddon on the Value of Art in Ethnology, 432; Dr. J. S. Phené on the Similarity of certain Ancient Necropoleis in the Pyrenees and in North Britain, 432; Dr. Manouvrier on Anthropometric Identification, 432; Criminal Anthropology, Dr. J. S. Clouston, 432; Dr. Benedikt, 433; Coiffure of a Kanaka Labourer, Sir William Turner, 433; Prehensile Power of Infants, Dr. Louis Robinson, 433; on the Contemporaneity of the Maori and the Moa, H. O. Forbes, 433; Human Osteometry, Dr. Garson, Sir William Turner, 433; Observations as to the Physical Deviations from the Normal as seen among 50,000 children, Dr. Francis Warner, 433; on some Facial Characters of the Ancient Egyptians, Prof. A. Macalister, 433; Ancient Skeletons from Medum, Egypt, Dr. Garson, 433
British Colonies, Elementary Geography of the, Geo. M. Dawson, F.R.S., and Alexander Sutherland, 100
British Earthworms, New, Rev. Hilderic Friend, 621
British Guiana, North-western District of, Everard im Thurn, 234
British Insects, Sketches of, Rev. W. Houghton, 540

Interference Methods, the application of, to Spectroscopic Measurement, Prof. Michelson, 385
International Conference on Chemical Nomenclature, Prof. H. E. Armstrong, F.R.S., 56
International Congress of Experimental Psychology, 362; F. W. H. Myers and James Sully, 261
International Congress of Orientalists, Ninth, 107, 456, 472
International Congress of Prehistoric Archæology and Zoology, the Coming Moscow, 108
International Geological and other Records, H. J. Johnston-Lavis, 441
International Time, Major the Hon. E. Noel, 423
International Zoological Record, an, F. A. Bather, 417
Invertebrata, the Physiology of the, Dr. A. B. Griffiths, F.R.S., 414
Inwards (R.), an Instrument for Drawing Parabolas, 93
Ireland, Dr. A. A. Rambaut, the new Astronomer-Royal for, 615
Iron: Iron and Steel Institute, 111, 471, 525; the Production of Pure Iron in the Basic Furnace, Colonel H. S. Dyer, 114; the Elimination of Sulphur from Iron, Ball and Wingham, 115, E. Saniter and J. A. Stead, 527; the Measurement of the Magnetic Properties of Iron, Thomas Gray, 163; on the Carburization of Iron, John Parry, 283; an Estimate of the Rate of Propagation of Magnetization in Iron, Prof. Fitzgerald, 385; Propagation of Magnetic Impulses along a Bar of Iron, V. A. Julius, 392; Iron in its Relation to Plant Life, Dr. Hans Molisch, 512; the Manufacture of Iron in its Relations with Agriculture, Sir Lowthian Bell, 525; the Alloys of Iron and Chromium, R. A. Hadfield, 526; Failures in Necks of Chilled Rolls, C. A. Winder, 527
"Island Life," Correction in, Dr. Alfred R. Wallace, 56
Isopods, the Early Development of the, Prof. J. Playfair McMurrich, 406
Italy, Earthquake in, 132
Ives (F. C.), in Colour Photography, Mr. John Carbutt on results achieved by, 13

Jackals, Hyde Clarke, 247
Jackals, Persons bitten by, 210
Jackson (Dr. Sheldon), Acclimatization of Reindeer in Alaska, 109
Jacoby (Harold), Rutherfurd Measures of Stars about β Cygni, 619
Jade Head found at Gignac, M. de Lapouge, 421
Jade Mines of Upper Burma, Dr. Noetling, 550
Jaffa-Jerusalem Railway, Completion of, 477
Jahrbuch der Chemie, 133
Jamaica, the Echinoderm Fauna of Kingston Harbour, G. W. Field, 40
Jamaica, Projected Laboratory of Marine Biology in, 176
Jamaica, Peripatus Re-discovered in, M. Grabham and T. D. A. Cockerell, 514
James (William), Text-book of Psychology, 1
Jamieson (Andrew), a Pocket-book of Electrical Rules and Tables, 486
Janet (Prof. P.), Curious Case of Sudden Loss of Memory, &c., (L'Aboulie), 363; Hallucination by Crystal Vision, 363

National Home Reading Society, the, 84
National Physical Laboratory, Discussion on a, Prof. Oliver J. Lodge, F.R.S., 382; Mr. Glazebrook, 383; Prof. von Helmholz, 383; Lord Kelvin, F.R.S., 383; Prof. Rücker, 383; Prof. Fitzgerald, 383
Natural History: John Hancock, Dr. Embleton, 255; South London Entomological Natural History Society, 46; Excursion of Victoria Field Naturalists' Club to the Grampians (Australia), 63; the Essex Field Club, 132; Bulletin de la Société des Naturaliste de Moscou, 236; Norfolk and Norwich Naturalists' Society, 450; Improvement in British Museum Natural History Collection, 473; Trinidad Field Naturalists' Club, 522; Manchester Field Naturalists' and Archæologists' Society's Visit to Buxton, 549; the Alleged "Aggressive Mimicry" of *Volucellæ*, William Bateson, 585
Natural Selection and Alternative Hypothesis, F. E. Beddard, F.R.S., Edward B. Poulton, F.R.S., 533
Navajo Indians, Evolution of House-building among the, Dr. Shufeldt, 451
Navy, Electricity in, H. E. Deadman, 337
Nebraska Sugar-Schools, the, 210
Nebula, Photographs of the Lyra Ring, Prof. Denza, 41
Nebula, the Trapezium in the Orion, Dr. L. Ambronn, 334
Nebulæ, Mr. Burnham, 87
Nebulæ, Catalogue of, 135
Nebulæ, Variable, E. E. Barnard, 211
Nebular Spectrum of Nova Aurigæ, Ralph Copeland, 464
Nebulous Star, a New, E. E. Barnard, 279
Necropoleis in the Pyrenees and in North Britain, on the Similarity of Certain Ancient, Dr. J. S. Phené, 432
Neesen's (Prof.) Researches on Motion of Loose Disks on Axis Rotating at High Speeds, 168
Nelson (E. M.), Penetration in the Microscope, 164; the Observation of Rings and Brushes of Crystals, 165
Nemertine, Freshwater, Note on the Occurrence of a, in England, W. Blaxland Benham, 611
Neptune, a Planet beyond, Prof. Forbes, 179; Mr. Roberts, 179
Neritidæ, Growth and Structure of Shell in, B. B. Woodward, 215
Nervous Complaints, a Shaking Cure for, Dr. Charcot, 451
Neutral Point in the Pendulum, Wm. Flinders Petrie, 293
New England during 1887, Thunderstorms in, R. de C. Ward, 1887, 555
New Guinea, Sir Wm. Macgregor's Explorations in, 110; the Piratical Tugere Tribe in, 258
New South Wales: a New Method of Rabbit-Destruction in, 161; Perfume-Flower-Farming in, 161; Royal Society of New South Wales, 191; the Carob-bean Tree in, F. Turner, 210; Fine Specimen of Saw Fish, Mr. Pedley, 257; New South Wales Rainfall during 1890, Mr. Russell, 473
New York Mathematical Society's Bulletin, 68, 236, 435
New York State, Execution by Electricity in, Dr. C. F. Macdonald, 256
New Zealand: Miss C. F. Gordon-Cumming's Paintings of Volcanic District in, 254; Sub-fossil Bones of Extinct Birds of New Zealand and the Chatham Islands, H. O. Forbes, 404; the Pliocene Mollusca of, Prof. F. W. Hutton, 474; Native New Zealand Birds, Earl of Onslow, 502; New Zealand System of Observing Earthquake Phenomena, G. Hogben, 594
Newall (H. F.), Nova Aurigæ, 489
Newton (Prof. Alfred, F.R.S.), Range of the Sanderling in Winter, 177, 222
Newton (E. T.), Palæontological Papers, 428
Newton's Rings, on a New Method of Viewing, T. C. Porter, 80
Niagara Falls to Buffalo, Mr. George Forbes, and the Cataract

Construction Company for the Transmission of Electrical Power from, 84
Nichols (E. L.), the Age-coating in Incandescent Lamps, 627
Nicolucci (Prof. G.), the Origin of the Ancient Egyptians, 162
Niger, Up the, Capt. A. F. Mockler-Ferryman, 512
Nitric Organisms, R. Warington, F.R.S., 151; Prof. Percy F. Frankland, F.R.S., 200
Nitrogen, Burning, W. Crookes, F.R.S., 185; Density of, Lord Rayleigh, F.R.S., 512
Nixon (R. C. J.), Elementary Plane Trigonometry, 488
Noble (Major-General), Death of, 84
Nock (Mr.), Wild Strawberries in Ceylon, 494
Noel (Major the Hon. E.), International Time, 423
Noetling (Dr.), the Amber and Jade Mines of Upper Burma, 549, 550
Nomenclature, the International Conference on Chemical, Prof. H. E. Armstrong, F.R.S., 56
Nomenclature of Units, Discussion on the, Prof. Oliver J. Lodge, F.R.S., 383
Nomenclature, Rules of, W. A. Herdman, 417
Norfolk and Norwich Naturalists' Society, 450
North America, Longmans' School Geography for, Geo. Chisholm and C. H. Leete, 585
North Atlantic, Prince of Monaco, 406
North Sea Fisheries, the; Mr. E. W. L. Holt's Investigations, 158
Norway, Handbook for Travellers in, 390
Norway and Sweden, Fall of Hail and Dust in, 108
Nova Aurigæ, 400; Prof. Konkoly, 17; Rev. A. Freeman, 453; Rev. T. E. Espin, 476; Prof. Küstner, 476; H. F. Newall, 489; Dr. F. Ristenpart, 496; Herr Cand. F. Kroeger, 496; Prof. E. E. Barnard, 496; H. Seelinger, 552; A. Belopolsky, 552, 576; Dr. J. Holetschek, 576; Photographic Magnitudes of, J. M. Schaeberle, 423; Nebular Spectrum of, Ralph Copeland, 464; the Spectrum of, Herr E. von Gothard, 620
Nova Scotia, Fossil Entomology of, Sir J. W. Dawson, F.R.S., 236
Nova Scotian Institute of Sciences, 550
Nuclei, on the Functions, Staining Reactions and Structures of, Dr. G. Mann, 403
Nuclein, on the Affinity of, for Iron and other Substances, Prof. G. Gilson, 405
Nucleus in the Vegetable Cell, Experimental Observations on the Functions of the, Dr. J. Clark, 404
Numbering the Hours of the Day, T. W. Backhouse, 392
Numeration of Asteroids, 372
Nuovo Giornale Botanico Italiano, 90, 436
Nürnberg, Exhibition at, by the German Mathematical Association, 204
Nyasaland, Industrial Resources of, John Buchanan, 407
Nyassaland, Mount Milanji in, Alexander Whyte, 482

Objectives, Mounting of, Prof. G. E. Hale, 452
Observations of Klinkerfues Reduced, the, Prof. Wilhelm Schur, 452
Observatories: Paris Observatory Report, Admiral Mouchez, 86; Annual Visitation of the Greenwich Observatory, 156; Mr. W. E. Plummer appointed Director of Liverpool Observatory, 276; Yale College Observatory Report, Mr. Brown, Dr. Elkin, 280; Vatican Pubblicazioni, vol. ii., 299; Madras Observatory, 301; Oxford University Observatory, 301; Solar Observations at the R. Osservatorio del Collegio Romano, Prof. Tacchini, 334; Natal Observatory, 362; the Staff at the Lick Observatory, 452; Daytime Seeing at the Lick Observatory, Henry Crew, 465; New Observatories, 476; Harvard Observatory, Appeal for Donations to Construct Great Refracting Telescope, E. C. Pickering, 548; Report of Mr. Tebbutt's Observatory, 576; Meteorological Observatories: the Sonnblick, 332; Hong Kong Observatory, Report of Director, 361
Ocean Currents at Chicago Exhibition, Model of, 451
Oceanic Circulation, Preliminary Account of, based on the *Challenger* Observations, Dr. A. Buchan, 383
Oceanography, Prince of Monaco, 406
Oceanography, Chemical, 408
Oceanography, Detailed, and Meteorology, 407
Odessa University, Memoirs of Mathematical Section of, 236
Odling (W.), London Water Supply for September, 1892, 617

Pearce (S. H.), Polybasite and Tennantite from Colorado, 310
Pearl Fishery of Gulf of California, C. H. Townsend, 333
Pearl-shell Diving at Tahiti, A. G. Howes, 301
Pearson (Prof. Karl), the Grammar of Science, 97, 199, 247
Peary Expedition, the Relief of the, 476
Peckham (G. W.), a Wave of Wasp-life, 611
Peddie (Dr. William), a Manual of Physics, 52; Experimental Proof that the Coefficient of Absorption is not affected by Density of Illumination, 385
Pedicularis of the Indian Empire, the Species of, D. Prain, 122
Pedley (Mr.), Fine Specimen of Saw Fish, New South Wales, 257
Peek (Cuthbert E.), Variable Star T Cassiopeiæ, 443
Penck's (Prof.) Proposed New Map of the Globe, 407
Pendulum on its Plane of Suspension, Nature of Rotation of Knife-edge of, G. Defforges, 263
Pendulum, Neutral Point in the, Wm. Flinders Petrie, 293
Penfield (S. L.), Polybasite and Tennantite from Colorado, 310
Penhallow (Prof.), an Improved Method of Labelling Slides, 69
Pennsylvania University, Endowment by General Wister of Museum of Anatomy at, 38
Pennsylvania, Devastation by Storm of Petroleum District, 133
Pensions, Civil List, for year ending June 20, 1892, 254
Peptone, Quantitative Determination of, L. A. Hallopteau, 436
Perak during 1891, Meteorology of, 473
Perigaud (M.), Influence of Place of External Thermometer in Observations of Zenith Distances, 263
Periodic Effect which the Size of the Bubbles has on their Speed of Ascent in Vertical Tubes containing Liquid, A, Dr. F. T. Trouton, 385
Periodic Variations of Alpine Glaciers, F. A. Forel, 386
Peripatus from St. Vincent, R. I. Pocock, 100
Peripatus, the Oviparity of the Larger Victorian, Dr. Dendy, 239
Peripatus Re-discovered in Jamaica, M. Grabham and T. D. A. Cockerell, 514
Perkin (W. H.), the Magnetic Rotation of Compounds supposed to contain Acetyl or of Ketonic Origin, 141
Perot (A.), the Measurement of the Dielectric Constant, 312; Experimental Illustration of Mirage, 617
Perrotin (M.), Observations of the Planet Mars, 482
Perry (John), Spinning Tops, 4
Perseids, the, W. F. Denning, 371
Perseids, the, J. Edmund Clark, 442
Persia, M. J. Bornmüller's Botanical Exploring Expedition in, 523
Persian Ideas in China, Rev. Dr. Edkins, 522
Personality, Alterations of, Alfred Binet, 219
Perthshire Society of Natural Science, Museum of, 472
Pests, Insect; Appearance of the Diamond-back Moth in Yorkshire and Northumberland, 108
Petrie (Wm. Flinders), Neutral Point in the Pendulum, 293
Petroleum District, Pennsylvania, Devastation by Storms of, 133
Petroleum Engines for Fog Signalling, D. A. Stevenson, 430
Petroleum Trade, the Caucasus, 333
Petrological Papers, Messrs. Ussher, Goodchild, Harker, Teall and Somerville, 428
Pettersson (Prof.), on the Hydrography of the Kattegat and Baltic, 408
Pflanze in ihren Beziehungen zum Eisen, die, Dr. Hans Molisch, 512
Pharyngeal Teeth in the Labridæ, Development of the, Prof. E. E. Prince, 405
Phené (Dr. J. S.), on the Similarity of Certain Ancient Necropoleis in the Pyrenees and in North Britain, 432
Philadelphia Academy of Natural Sciences Expedition to Greenland in 1891, Insects taken by, 40
Philadelphia Loan Collection of Objects used in Worship, 84
Philadelphia, Zoological Society of, 133
Philippine Islands, Geographical Distribution of the Land-Mollusca of the, Rev. A. H. Cooke, 142
Philippine Islands: Volcanic Eruption at Great Sangir, 287, 299, 332
Philippon (G.), Effect of Sudden Release on Animals placed in Compressed Air, 312

Phillott (Captain D.), Curious Case of Malformation in Beak of Indian Parrakeet, 190

Philology: Alleged Discovery by Mr. Cyrus Thomas of the Key to the Central American Inscriptions, 160; Fuegan Languages, Dr. Brinton, 278

Philosophische Studien, Wundt's, 133

Phipson (T. L.), Fossil Wood containing Fluoride, 580

Phosphoroscope for use with the Electric Spark, Lenard's, 484, 618

Photography: Beginner's Guide to Photography, 6; Photography in Colours, 12; Mr. John Carbutt on Results achieved by Mr. F. E. Ives in Colour Photography, 13; the Photography of Colours, G. Lippmann, 24; Colour Photography, Prof. Vogel's Method, 263; Photographic and Visual Magnitudes of Stars, Prof. J. C. Kapteyn, 41; Photographs of the Lyra Ring Nebula, Prof. Denza, 41; Photographs of Flying Bullets, Mr. Boys, 45; Photographs of Coral Reefs and Marine Fauna of Great Barrier District of Australia, W. Saville-Kent, 45; Photographic Measures of the Pleiades, 161; Method of Examination of Photographic Objectives at Kew Observatory, Major L. Darwin, 188; the Process of Enlarging, J. A. Hodges, 210; Proposed National Photographic Record Survey, W. J. Harrison, 209; Lunar Photography, Dr. L. Weinek, Prof. Holden, 257; Dr. Lohse's Photographs of Sun-Spots, 258; Photographic Map of the Heavens, 274; Photographic Chart of the Heavens, H. C. Russell, 576; Refraction in Micrometric and Photographic Measures, Dr. S. C. Chandler, 401; Photography and Surveying, Colonel Tanner, 407; Determination of Longitude by Photography, Dr. H. Schlichter, 407; Photographic Magnitudes of Nova Aurigæ, J. M Schaeberle, 423; Photography of Spectra in Natural Colours, H. Krone, 449; Photographs of Solar Phenomena, Prof. G. E. Hale, 452; Solar Photography, Prof. G. E. Hale, 455; Traité Encyclopédique de Photographie, Charles Fabre, 464; Minor Planets Discovered by Photography, 576; Discovery of Three New Planets by Photography, 619; Mr. J Gaultier's System of Photographic Surveying, 525; Photographic Dry Plates, 588; Researches in Stellar Parallax by the Aid of Photography, Prof. Charles Pritchard, F.R.S., 612

Photometric Observations of the Sun and Sky, William Brennand, 284

Phycological Memoirs, 75

Physics: On a decisive Test-Case disproving the Maxwell-Boltzmann Doctrine respecting distribution of Kinetic Energy, 21; Physical Society, 23, 93, 164, 214, 236, 263; on a Proposition in the Kinetic Theory of Gases, Rev. H. W. Watson, F.R.S., 29; Waterston's Theory of Gases, 30; a Manual of Physics, William Peddie, 52; a Question in Physics, Prof. H. A. Hazen, 55; Radiation of Atmospheric Air, C. C. Hutchins, 67; Atmospheric Radiation of Heat and its Importance in Meteorology, Prof. Cleveland Abbe, 67; the Cause of the Absence of Hydrogen from the Earth's Atmosphere and of Water and Air from the Moon, Dr. G. J. Stoney, F.R.S., 71; Mathematics used in Physics, Victor Von Lange, 73; Lord Kelvin's Test-Case on the Maxwell-Boltzmann Law, Edw. B. Culverwell, 76; on some Phenomena connected with Cloudy Condensation, John Aitken, F.R.S., 90; the Potential of an Anchor Ring, F. W. Dyson, 92; Study of Physical and Chemical Phenomena under Influence of very Low Temperatures, Raoul Pictet, 144; a means of bringing Two Non-miscible Liquids into Intimate Contact in definite proportions, Paul Marix, 144; Historical Summary of our Knowledge of the Connection between Ether and Matter, Prof. O. J. Lodge, F.R S., 164; the Hypothesis of a Liquid Condition of the Earth's Interior considered in connection with Darwin's theory of the Genesis of the Moon, Osmond Fisher, 166; Prof. Neesen's Researches on motion of Loose Disks on Axis Rotating at High Speeds, 168; Relation of Dimensions of Physical Quantities to Directions in Space, W. Williams, 237; Variations in Temperatures of Water suddenly compressed to 500 atmospheres between 0° and 10°, Paul Galopin, 240; Elements of Physic, C. E. Fessenden, 245; Experiments at the Eiffel Tower on Falling Bodies and Air-Resistance, L. Cailletet and E. Colarteau, 262; the Laws of Motion, part ii., Prof. Tait, 262; Nature of Rotation of Knife-Edge of Pendulum on its plane of suspension, G. Defforges, 263; Experiments on the Measurement High Temperatures, Dr. Wien, 263; a Treatise on hysical Optics, A. B. Basset, F.R.S., Arthur Schuster, 267; Basset's Physical Optics, A. B. Basset, 315; Determination of Density of Gases, H. Moissan and H. Gautier, 288; Measurement of Absolute Intensity of Gravity at Breteuil, G. Defforges, 288; Change of Heat Conductivity on passing isothermally from Solid to Liquid, C. Barus, 310; Opening Address in Section A of the British Association by Prof. Arthur Schuster, F.R.S., 323; Employment of Calorimetric Shell, M. Berthelot, 339; Velocity of propagation of Electromagnetic Undulations in Insulating Media, R. Blondlot, 340; Physics at the British Association, 382; Opening Address in Section A, by Prof. Arthur Schuster, F.R.S., at the British Association, 323; Discussion on a National Physical Laboratory, Prof. Oliver J. Lodge, F.R.S., 382; R. T. Glazebrook, F.R.S., Prof. Fitzgerald, F.R.S., 383; Discussion on Nomenclature of Units, 383; Report on Underground Temperature, 383; Report on the Discharge of Electricity from Points, 383; Report on Electrical Standards, 383; Wire Standards of Electric Resistance, Dr. Lindeck, 383; Dr. Kahle on the Clark Cell, 383; Preliminary Account of Oceanic Circulation based on the *Challenger* Observations by Dr. A. Buchan, 383; Physical Condition of the Waters of the English Channel, H. V. Dickson, 384; on Primary and Secondary Cells in which the Electrolyte is a Gas, Prof. Schuster, F.R.S., 384; on Leaky Magnetic Circuits, Dr. du Bois, 384; Experiments on the Electric Resistance of Metallic Powders, Dr. Dawson Turner, 384; on the Stability of Periodic Motions, Lord Kelvin, F.R.S., 384; on the Specific Conductivity of Thin Films, Profs. Reinold and Rücker, 384; a Contribution to the Theory of the Perfect Influence Machines, J. Gray, 384; Experiments with a Ruhmkorff Coil, Magnus Maclean and A. Galt, 384; the Application of Interference Methods to Spectroscopic Measurement, Prof. A. Michelson, 385; on a Periodic Effect which the Size of Bubbles has on their Speed of Ascent in Vertical Tubes containing Liquid, Dr. F. T. Trouton, 385; on a Method of Determining Thermal Conductivities, C. H. Lees, 385; a Magnetic Curve Tracer, Prof. Ewing, 385; on a Magnetic Balance and its Practical Use, Prof. du Bois, 385; on Earth Current Storms in 1892, W. H. Preece, 385; on the Dielectric of Condensers, W. H. Preece, 385; on Polarizing Gratings, Prof. du Bois, 385; the Volume Effects of Magnetism, Dr. C. G. Knott, 385; an Estimate of the Rate of Propagation of Magnetization of Iron, Prof. Fitzgerald, 385; Experimental Proof that the Co-efficient of Absorption is not Affected by Density of Illumination, Dr. W. Peddie, 385; on Dispersion in Double Refraction due to Electric Stress, Dr. John Kerr, 385; on a Delicate Calorimeter, J. A. Harker and P. J. Hartog, 385; on Graphic Solutions of Dynamical Problems, Lord Kelvin, 385; Reduction of every Problem of Two Freedoms in Conservative Dynamics to the Drawing of Geodetic Lines on a Surface of given Specific Curvature, Lord Kelvin, 386; Application of Measurement of Density to Determination of Atomic Weight of Oxygen, A. Leduc, 387; Scientific Measuring Instruments, General Ferrero, 388; Propagation of Magnetic Impulses along a Bar of Iron, V. A. Julius, 392; on the Relative Contamination of the Water-Surface by Equal Quantities of Different Substances, Miss Agnes Pockels, 418; Investigation of the Phenomena which accompany the Burning of Carbon and Phosphorus in Oxygen, H. Brereton Baker, 431; Observations as to the Physical Deviations from the Normal, as seen among 50,000 children, Dr. Francis Warner, 433; Heat of Combustion of some Chlorine Compounds, MM. Berthelot and Matignon, 436; Trattato di Fisico-Chimica secondo la Teoria Dinamica, Prof. di Mombello, 439; Generalization of "Mercator's" Projection performed by Aid of Electrical Instruments, Lord Kelvin, F.R.S., 490; Aberration Problems, Dr. Oliver J. Lodge, F.R.S., 497; Calorific Distribution of Sun heat at surface of Northern and Southern Hemispheres of Earth, Le G. de Tromelin, 508; the Temperature of the Human Body, L. Cumming, 541; Measurement of High Temperatures, L. Holborn and W. Wien, 602; Expansion of Gases at Low Pressures, G. Melander, 602; Specific Gravity and Fusion of Ice, J. von Zakrzevski, 602; Thermal Radiation in Absolute Measure, Dr. J. T. Bottomley, F.R.S., 603; a Redetermination of the Mechanical Equivalent of Heat, C. Miculescu, 618; Polarization of Light of various Colours by Atmosphere, N. Piltschikoff, 627

Physiology: the Temperature of the Brain, 17; Dr. J. S. B. Sanderson appointed Waynflete Professor at Oxford, 37;

Movements of Minute Organisms Analysed by Chronophotography, M. Marey, 47; Residual Life, Gautier and Landi, 71; the Relations of the Motor Muscles of the Eyes to Facial Expression, Dr. G. T. Stevens, 86; the Embryology of *Angiopteris evecta*, J. B. Farmer, 92; the Shoulder-girdle in Ichthyosauria and Sauropterygia, J. W. Hulke, F.R.S., 93; the Development of the Stigmata in Ascidians, Walter Garstang, 93; Experiments to Determine Cause of Difference in Latent Period during Direct and Indirect Stimulation of Muscles, Dr. Boruttau, 96; Physiology of the Glands of Bohadsch in the Aplysiidæ, G. F. Mazzarelli, 163; the Products of the Residual Life of the Tissues, Gautier and Landi, 167; Experiments on Respiration under Reduced Atmospheric Pressure, Prof Loewy, 168; Williams's Frog Heart Apparatus, Prof. R. Kobert, 177; the Brain of the Gorilla, Dr. H. C. Chapman, 229; Physiological Effects of Mountain Climates, M. Viault, 240; the Rotatory Movements of the Human Vertebral Column, Dr. A. W. Hughes, 262; Berlin Physiological Society, 263, 340; Dr. Monti's Experiments on Absorption of Oxygen by Tissues after Death, 263; Dr. Lillienfeld's Investigations on the Distribution of Phosphorus in Various Tissues, 263; a Phenomenon of Human Respiration, Prof. Litten, 263; Anatomy, Physiology, Morphology, and Development of the Blow-fly (*Calliphora erythrocephala*), B. Thompson Lowne, 267; Effect of Sudden Release on Animals placed in Compressed Air, G. Philippon, 312; Action of Paraffin Nitrites on Muscular Tissue, Dr. J. T. Cash, F.R.S. and W. R. Dunstan, 339; Pigment Cells of Retina, I. S. Boden and F. C. Sprawson, 339; Primitive Segmentation of Vertebrate Brain, B. H. Waters, 330; Oscula and Anatomy of *Leucosolenia clathrus*, E. A. Minchin, 339; Innervation of Cerata of some Nudibranchiata, Dr. W. A. Herdman and J. A. Clutt, 339; the Sense of Temperature, Dr. Dessoir, 340; Effect of Muscular Exertion on Alkalinity of Blood of Carnivora as compared with Herbivora, Prof. Zuntz, 340; Waste of Nitrogen from Excessive Fatigue, MM. Chibret and Huguet, 364; Prof. Waymouth Reid on Vital Absorption, 403; Prof Rosenthal on Animal Heat and Physiological Calorimetry, 403; Dr. Lockhart Gillespie en Proteid-hydrochlorides, 403; Dr. E. W. Carlier on the Hibernating Gland of the Hedgehog, 403; Dr. G. Mann on the Functions, Staining Reactions and Structures of Nuclei, 403; the Physiology of the Invertebrata, Dr. A. B. Griffiths, F.R.S., 414; Effects of Absence of Light upon Animal Life, 421; International Congress of Physiologists, 449, 477; Removal of the Thyroid in the White Rat, H. Cristiani, 484; the Active Albumen in Plants, 491; Physiology of Epilepsy, M Brown-Séquard, 507; Echinochrome, a Respiratory Pigment, A. B. Griffiths, 508; the Temperature of the Human Body, L. Cumming, 541; G. M. Stewart, Dr. W. Hale White, 588; on the Cause of Physiological Action at a Distance, Prof. L. Errera, 555: Respiratory Globuline in the Blood of Chitons, A. B. Griffiths, 580; the Comparative Physiology of Respiration, Prof. Simon Henry Gage, 598; the Movements of the Heart studied by Chronophotography, M. Marey, 604; the Structure and Functions of the Brain and Spinal Cord, Victor Horsley, F.R.S., 606; the Physiological Effect of a Farinaceous Diet on Animals, Prof. Voit, 618

Retina, the Blood-vessels and Lymphatics of the, Dr. J. Musgrove, 404

REVIEWS *and* OUR BOOKSHELF:—
  The Human Mind: a Text-book of Psychology, James Sully, 1
  Hand-book of Psychology: Feeling and Will, J. M. Baldwin, 1
  Text-book of Psychology, William James, 1
  Dynamics of Rotation: an Elementary Introduction to Rigid Dynamics, A. M. Worthington, 4
  Spinning Tops, John Perry, 4
  The Fauna of British India, including Ceylon and Burmah, W. T. Blanford, F.R.S., 5
  Tanganyika: Eleven Years in Central Africa, Edward Coode Hore, 6

Beginners' Guide to Photography, 6
Quain's Elements of Anatomy, Edited by E. A. Schäfer, F.R.S., and G. D. Thane, 6
Brachiopoden der Alpinen Trias, A. Bittner, 25
Elements of Economics of Industry, Prof. Alfred Marshall, 27
Elements of Materia Medica and Therapeutics; including the whole or the Remedies of the British Pharmacopœia of 1885 and its Appendix of 1890, C. E. Armand-Semple, 28
Elementary Lessons in Heat, S. E. Tillman, 28
The Tel el-Amarna Tablets in the British Museum, with Autotype Facsimiles, 49
A Manual of Physics, William Peddie, 52
The Dietetic Value of Bread, John Goodfellow, 54
Graduated Mathematical Exercises, A. T. Richardson, 54
Bibliothek des Professors der Zoologie und vergl. Anatomie, Dr. Ludwig von Graff, in Graz, 54
The Canadian Guide-book, Charles G. D. Roberts, 54
Einleitung in die Theoretische Physik, Victor von Lange, 73
Phases of Animal Life, Past and Present, R. Lydekker, 74
Silk Dyeing, Printing, and Finishing, George Hurst, 75
Phycological Memoirs, George Murray, 75
Live Stock, Prof. Wrightson, 76
The Grammar of Science, Karl Pearson, M.A., 97
Laboratory Practice: a Series of Experiments on the Fundamental Principles of Chemistry, Josiah Parsons Cooke, 99
Elementary Geography of the British Colonies, George M. Dawson, F.R.S., and Alexander Sutherland, 100
Farmyard Manure, C. M. Aikman, 100
Annals of the Royal Botanic Garden, Calcutta: (i.) Species of Pedicularis of the Indian Empire and its Frontiers, D. Prain; (ii.) the Magnoliaceæ of British India, G. King, F.R.S.; (iii.) the Genus Gomphostemma, D. Prain; (iv.) the Species of Myristica of British India, G. King, W. Botting Hemsley, 122
Mathematical Recreations and Problems of Past and Present Times, W. W. Rouse Ball, 123
Soils and Manures, J. H. M. Munro, 125
Catalogue of the Specimens Illustrating the Osteology of Vertebrated Animals, Recent and Extinct, contained in the Museum of the Royal College of Surgeons of England, R. Bowdler Sharpe, 125
A Treatise on Analytical Statics, Edward John Routh, F.R.S., Prof. A. G. Greenhill, F.R.S., 145
The Elementary Part of a Treatise on the Dynamics of a System of Rigid Bodies, E. J. Routh, F.R.S., Prof. A. G. Greenhill, F.R.S., 145
Supplementary Appendix to Travels amongst the Great Andes of the Equator, Edward Whymper, H. J. Elwes, 147
A History of Epidemics in Great Britain from A.D. 664 to the Extinction of the Plague, Charles Creighton, 148
Mineralogy, Frederick H. Hatch, 149
To the Snows of Tibet through China, A. E. Pratt, 150
Analyse des Vins, Dr. L. Magnier de la Source, 170
An Introduction to Modern Therapeutics, T. Lauder Brunton, M.D., 172
Elementary Hydrostatics, W. H. Besant, F.R.S., 172
The Threshold of Science, C. R. Alder Wright, F.R.S., 173
Key to J. B. Lock's Elementary Dynamics, G. H. Lock, 173
English Botany, N. E. Brown, James Britten, 197
Bacteriologisches Practicum zur Einführung in die practisch-wichtigen bacteriologischen Untersuchungsmethoden für Aerzte, Apotheker, Studirende, Dr. W. Migula, Mrs. Grace C. Frankland, 198
Neue Rechnungsmethoden der Höheren Mathematik, Dr. Julius Bergbohm, 199
Neue Intergrationsmethoden auf Grund der Potenzial-, Logarithmal-, und Numeralrechnung, Dr. J. Bergbohm, 199
An Elementary Course in Theory of Equations, C. H. Chapman, 199
The System of Mineralogy of James Dwight Dana, 1837–68; Descriptive Mineralogy, Edward Salisbury Dana, 217
An Introduction to the Study of the Differential and Integral Calculus, Axel Harnack, Prof. A. G. Greenhill, F.R.S., 218
Les Altérations de la Personnalité, Alfred Binet, 219
Volcanoes: Past and Present, Edward Hull, F.R.S., 220
Encyclopédie scientifique des Aide-mémoire, 221
Résistance des Matériaux, M. Duquesnay, 221

A Text-book of Agricultural Entomology, Eleanor A. Ormerod, 561
The Optical Indicatrix and the Transmission of Light in Crystals, L. Fletcher, 581
Contributions to Horticultural Literature, William Paul, Dr. Maxwell T. Masters, F.R.S., 582
Life in Motion; or, Muscle and Nerve, John Gray McKendrick, F.R.S., 583
Principles and Practice of Plumbing, S. Stevens Hellyer, 584
A Lecture Course of Elementary Chemistry, H. T. Lilley, 585
Longmans' School Geography for North America, G. H. Chisholm and C. H. Leete, 585
Garden Design and Architects' Gardens, W. Robinson, 585
Fur-bearing Animals in Nature and Commerce, Henry Poland, 605
The Structure and Functions of the Brain and Spinal Cord, Victor Horsley, F.R.S., 606
Electrical Engineering as a Profession, and How to Enter it, A. D. Southam, 608
A Treatise on Hygiene and Public Health, 609
Lehrbuch der Botanik nach dem gegenwärtigen Stand der Wissenschaft, Dr. A. B. Frank, 610
Arithmetrical Chemistry, C. J. Woodward, 610
Lessons in Heat and Light, D. E. Jones, 610
Elements of Magnetism and Electricity, John Angell, 610
Beiträge zur Theorie und Praxis der Desinfection, Prof. J. Maschek, Mrs. Percy Frankland, 613

Reyer (Prof. E.), on the Causes of the Deformation of the Earth's Crust, 224
Reynolds (J. E.), Action of Silicon Tetrachloride on substituted Phenylamines, 22
Reynolds (Dr. J. Emerson, F.R.S.), Fuels and their Use, 527
Rhinoceros, the White, W. L. Distant, 29
Richards (Dr.), Re-determination of the Atomic Weight of Copper, 134
Richardson (A. T.), Graduated Mathematical Exercises, 54
Richardson (Dr. B. W.), French and English Methods of Sanitation compared, 299
Richet (Ch.), Tuberculous Vaccination of Dogs, 168
Richmond (H. D.), Masrite and Masrium, 94; Geology of the Nile Valley, 190
Ridgway on the Humming-Birds, R. W. Shufeldt, 465
Rigaux (E.), Geology of the Bas Boulonnais, 109
Rigg (James), at Portrush, 418
Riley (Prof. C. V.), Locusts in America, 256; Directions for Collecting and Preserving Insects, 416; Fertilization of the Fig and Caprification, 455; the Transmission of Acquired Character through Heredity, 504
Rings, Newton's, on a new Method of Viewing, T. C. Porter, 80
Rings, Saturn's, Rev. A. Freeman, 150
Ristenpart (Dr. F.), Nova Aurigæ, 496
River, an Acoustic Method whereby the Depth of Water in a, may be Measured at a Distance, Fred. J. Smith, 246
Roberts (Mr.), a Planet beyond Neptune, 179
Roberts (Charles G. D.), the Canadian Guide Book, 54
Roberts-Austen (Prof. W. C.), an Apparatus for Autographically Recording the Temperature of Furnaces, 526
Robertson (David) and John Gall, Popular Readings in Science, 291
Robertson (Prof. Geo. Croom), Death of, 520
Robinson (Dr. Arthur), Observations on the Development of the Posterior Cranial and Anterior Spinal Nerves in Mammals, 405
Robinson (Rev. J. A.), Association founded for Study of Hausa Language and People in Commemoration of, 572
Robinson (Dr. Louis), Prehensile Power of Infants, 433
Robinson (W.), Garden Design and Architects' Gardens, 585
Rock Structure, Sir Archibald Geikie, F.R.S., 317
Rogers (Prof. W. A.), the Hardness of Diamonds not Perceptibly Reduced by Cutting and Polishing, 257; a Standard Yard and Measure on Polished Steel, 455
Rolland (G.), Contributions to Knowledge of Saharian Climate, 144
Rolls, Chilled, Failures in Necks of, C. A. Winder, 527
Romanes (Dr. Geo. J., F.R.S.), Hairlessness of Termina Phalanges in Primates, 247
Romano, Solar Observations at the R. Osservatorio del Collegio, Prof. Tacchini, 334
Rome, R. Accademia dei Lincei, 387
Rome, Solar Observatious at, Prof. Tacchini, 476, 524
Roscoe (Sir H. E., F.R.S.), Watts' Dictionary of Chemistry, M. M. Pattison Muir and Forster Morley, 242; Obituary Notice of Dr. Carl Schorlemmer, F.R.S., 394
Rosenbaum (Herr), a new Theory of Sleep, 595
Rosenthal (Prof.), on Animal Heat and Physiological Calorimetry, 403
Rotation, Dynamics of: an Elementary Introduction to Rigid Dynamics, A. M. Worthington, 4
Roumania, Earthquake in, 594
Roumeguère (M.), Death of, 61
Rousseau (G.), a Hydro-silicate of Cadmium, 144
Routh (Edward John, F.R.S.): a Treatise on Analytical Statics, 145: the Elementary Part of a Treatise on the Dynamics of a System of Rigid Bodies, 145
Row (Narasinga), Death of, 176
Rowland-Brown (H.), a *Colias edusa* Butterfly in London, 228
Royal Agricultural Society's Journal, 262
Royal Dublin Society, 71, 167
Royal Geographical Society, 258, 552; Anniversary Meeting of the, President's Address, 87; Royal Geographical Society's Soirée, 180
Royal Institution, Gift of Mr. Thomas Hogkins for Promotion of Scientific Research to, 572
Royal Meteorological Society, 95, 191
Royal Microscopical Society, 69, 165
Royal Society, 21, 69, 90, 140, 163, 187, 236, 339, 603; Royal Society's Committee on Colour Vision, Report of the, 33; Selected Candidates, 35; Royal Society's Soirée, 44; Model Illustrating General Phenomena of Explosions through Dust Particles, in Explanation of Colliery Explosions, Prof. T. E. Thorpe, 44; Miner's Safety Lamp converted into Instrument for detecting Coal-damp, Prof. Clowes, 44; Vacuum Tubes without Electrodes, Dr. Bottomley, 44; Musical Sands, C. Carus-Wilson, 44; Apparatus for measuring Colour-blindness, Brudenell Carter, 44; Captain Weir's Azimuth Diagram, 44; Electric Sparks in and to Water, Prof. Oliver Lodge, 44; Electric Retina, Prof. Oliver Lodge, 44; Experiments of Electric Currents of High Potential and Extreme Frequency à la Tesla, W. Crookes, 44; New Electrical Method for determining very High Temperatures, Prof. H. Le Chatelier, 45; Electric Tram Chronograph, Rev. F. J. Smith, 45; Photographs of Flying Bullets, Mr. Boys, 45; Photographs, &c., Illustrating Coral Reefs and Marine Fauna of Great Barrier District of Australia, W. Saville-Kent, 45; the Yearly Admissions to the Royal Society, Lieut.-General R. Strachey, F.R.S., 116; the Ladies' Conversazione of the Royal Society, 184
Royal Society of New South Wales, 191
Royal Society of Victoria, 459

Rubens (H.), Refraction of Rays of Great Wave-length in Rock Salt, Sylvine and Fluorspar, 483
Rücker (Prof., F.R.S.), the Discussion on a National Physical Laboratory, 383 ; on the Specific Conductivity of Thin Films, 384
Rudge (W. A.), a Viper Bite, 270
Ruffer (Armand), the Imperial Institute at St. Petersburg, 520
Ruhmkorff Coil, Experiments with a, Magnus Maclean and A. Galt, 384
Rumex occurring North of Mexico, Revision of the Species of, W. Trelease, 40
Runge (Prof. C.), the Line Spectra of the Elements, 100, 200, 247
Russell (Francis C.), Induction and Deduction, 586
Russell (H. C.), Photographic Chart of the Heavens, 576; Proposed School of Practical Astronomy, 496
Russell (Hon. Rollo), Epidemics, Plagues and Fevers, their Causes and Prevention, 413
Russia, Mercury Mining in, 86
Russian Monthly Meteorological Bulletins, Two New, 38
Rutherfurd (Lewis Morris), Obituary Notice of, 206
Rutherford (Prof. William, F.R.S.), Opening Address in Section D of the British Association, 342
Rutherfurd Measures of Stars about β Cygni, Harold Jacoby, 619

Sabatier (Prof. Armand), Essai sur la Vie and la Mort, 560
Saccharine, Ants and, H. Devaux, 573
Saharian Climate, Contributions to Knowledge of, G. Rolland, 144
St. Andrews Marine Laboratory, 369
St. Bernard, Great, Table showing Behaviour with regard to Cold of Small Lake at, Prof. Forel, 371
St. Gervais les Bains, Terrible Glacier Slip Disaster at, 254; Theories of the Cause of, Profs. Duparc and Forel, 299; Causes of, 420; the Lava of July 12, 1892, P. Demontzey, 387
St. John's, the Cause of the Great Fire at, 295
St. Petersburg: Bulletin de l'Academie des Sciences de St. Petersbourg, 68; Memoirs of St. Petersburg Society of Naturalists, 68; Dr. A. F. Batalin appointed Director of Botanic Garden at, 107; the Imperial Institute at, Armand Ruffer, 520; Laying Foundation Stone of New Chemical Laboratory of St. Petersburg University, 592
St. Vincent, *Peripatus* from, R. I. Pocock, 100
Sakurai (J.), Determination of Temperature of Steam from Boiling Salt Solutions, 94; Note on an Observation by Gerlach of the Boiling-points of a Solution of Glauber's Salt, 94
Sal-Soda Manufacture in United States, Prof. C. F. Mabery, 332
Salamander, on the Relationships and Rôle of the Archoplasmic Body during Mitosis in the Larval, J. E. S. Moore, 404
Salet (G.), Stokes's Law (Spectrum Analysis), its Verification and Interpretation, 364
Salmon Fungus, the Effect of Sea-water on the Vitality of the, A. P. Swan, 405
Salomons (Sir David), Optical Projection, 625
Samoan Calendar, Change in, 552
Samson (G. Gordon) Bees for Pleasure and Profit, W. Tuckwell, 510
Sand, Musical, T. S. Hall, 279; C. Carus-Wilson on, 44, 316
Sanderling, Range of the, in Winter, Prof. Alfred Newton, F.R.S., 177, 222
Sanderson (Dr. J. S. B.), appointed Waynflete Professor of Physiology at Oxford, 37
Sangir, Volcanic Eruption at Great, 287; George Ormsby, 457
Sanitation, French and English Methods Compared, Dr. B. W. Richardson, 299
Sanitation, the Victorian Era, the Age of, Sir Charles Cameron, 472
Sanitary Inspectors' Association, General Meeting, 299
Sanitary Institute, the Thirteenth Congress of the, 449; Sanitary Institute and its Transactions in Review, 463; Sir Charles Cameron's Presidential Address, 472
Saniter (E.), the Elimination of Sulphur from Iron, 527
Sanscrit Birch-bark Manuscripts, Discovery by Lieut. Bower of, Dr. Hoerale, 370
Sarasin (M.), Production of Hertz Oscillator Spark in Liquid Dielectric instead of Air, 532
Satellite, Jupiter's Fifth, Prof. E. E. Barnard, 620
Saturn's Rings, M. Bigourdan, 110; Rev. A. Freeman, 150
Saville-Kent (W.), Photographs, &c., Illustrating Coral Reefs and Marine Fauna of Great Barrier District of Australia, 45; the Great Barrier Reef of Australia, 523
Saw Fish, New South Wales, Fine Specimen of, Mr. Pedley, 257
Scacchi (Prof. E.), the Crystallography of Certain New Salts (Fluoximolybdates of Copper and Zinc) obtained by Prof. F. Mauro, 162
Scale for Measurement of Gas Pressures, Orme Masson, 294
Schaeberle (J. M.), Photographic Magnitudes of Nova Aurigæ, 423; a New Variable Star, 620

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

" To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, MAY 5, 1892.

TEXT-BOOKS OF PSYCHOLOGY.

The Human Mind: a Text-book of Psychology. By James Sully, M.A., LL.D. Two Vols. (London: Longmans, 1892.)

Hand-book of Psychology: Feeling and Will. By James Mark Baldwin, M.A., Ph.D. (London: Macmillan, 1891.)

Text-book of Psychology. By William James. (London: Macmillan, 1892.)

IN his treatise on the "Human Mind," Mr. Sully has not attempted to supplant, but rather to supplement, his own admirable "Outlines of Psychology." The method in the two works is the same, and the arrangement of the subject-matter, though it differs slightly in some details, is, on the whole, essentially and in principle similar. A chapter has been added on the physical basis of mental life, dealing briefly with the nervous system and with neuro-psychical correlations. But the author wisely refers his readers to text-books of physiology or to manuals of physiological psychology for a full treatment of these matters. He also gives an adequate account of the recent experimental researches on the nature and conditions of some of the simpler responsive activities, but is not blind to the difficulties and uncertainties of this so-called experimental psychology.

It is well known that Mr. Sully lays great stress on the genetic method in psychology.

> "It is evident," he says, "that we require a knowledge of these psychical elements [reached by analysis] and of the laws of their combination, in order to account for the complex products of the mature human consciousness. Now, the perfect account of a thing means the history of that thing from its first crude to its completed form. When the psychologist has succeeded by analysis, aided by objective observation and hypothesis, in obtaining the requisite data, he proceeds to reconstruct the course of psychical development."

From the standpoint of biology and evolution, this genetic aspect of psychology is of especial importance, and we cannot be too grateful to Mr. Sully for his able, clear-headed, and, on the whole, cautious presentation of this view of the matter. But it is one which, as Mr. Sully himself well knows, is of peculiar difficulty. Few of us remember anything of the genesis of our modes of psychological procedure in the early days of our life; and when we do remember scraps here and there, we are only too apt to interpret them in terms of our adult procedure, with which we are so much more familiar. It is, moreover, well nigh impossible for the psychologist to realize the nature of the psychical processes of the child, so that infant psychology is a field wherein we may suppose much and can prove little. Mr. Sully again and again appeals to the supposititious child.

> "The child, for example," he says, "begins to note that some varieties of living things, *e.g.* flies or birds, die. He then compares these results, and, extracting the common relation, finds his way to the more comprehensive generalization, 'All animals die.' Later on he compares this result with what he has observed of flowering and other plants, and so reaches the yet higher and more abstract generalization, 'All living things die.'"

Of course there may be a child here and there who proceeds, or, in the absence of all instruction in the matter, might proceed, thus. But children and uneducated persons very rarely reach a general and universal concept, properly so called. The child notes that its pets and other animals die or are killed: this begets a stronger and stronger expectation that other animals will likewise die or be killed some day; and the expectation may rise to practical certainty without anything like a universal concept taking even vague and indefinite shape in the mind. We therefore question the statement that "by induction the child reaches a large number of general or universal judgments," though it is unquestionable that he may have a large number of expectations which the logician may cast in universal form. He may even state them in universal form himself, and say, "Animals die," "Apples have pips," the language he uses being here, as in so many cases, in advance of his conceptions.

In the discussion of the development of the moral sentiment, the distinctively moral feeling is perhaps hardly differentiated with sufficient care from the merely prudential. The prudential does not pass up into the moral on the same line of development; but the prudential and the moral are separate and sometimes widely divergent lines of development. It is sometimes said that the prudential is self-centred while the moral is social. But is not what is socially right different from what is socially prudent? Or, in other words, is not morality something other than social prudence? Remorse for wrong has a different psychological quality from regret for error, no matter what the social implications of the error may be. Mr. Sully does not seem to have sufficiently brought out this distinction in his account of the genesis of the moral sense.

But though there may be room for some difference of opinion as to the exact course of genetic development by which our more complex and more highly evolved psychological states have been reached, there can be no question that Mr. Sully's painstaking and thoughtful discussion of their possible or probable mode of evolution is and will long remain of real and sterling value. No living writer has paid more attention to this important aspect of psychology.

There is one more point on which we may comment before we pass on to Prof. Baldwin's work. It is the doctrine of residual fusion.

> "The simplest form of assimilation," we read, "is to be found in that process by which a present sensation (or sensation complex) is re-apprehended or 'recognized' as something familiar. . . . What takes place here is the calling up by a present sensation of the trace or residuum of a past sensation (or sensations), which trace merges in or coalesces with the new sensation, being discernible only through the aspect of familiarity which it imparts to the sensation. . . . We have to conceive of the nervous process somewhat after this manner. A given central element or cluster of elements is re-excited to a functional activity similar to that of a previous excitation. The residuum of this previous activity or surviving 'physiological disposition' somehow combines with and modifies the new activity; which blending of nervous processes has for its psychical correlative the peculiar mode of consciousness known as recognition, sense of familiarity, or identification. Here, however, our physiological psychology seems to be more than usually conjectural."

And again—

> "In recognition the percept and the image are fused, the presence of the latter being indicated merely in the peculiar appearance of familiarity which the percept assumes."

This so-called "fusion" of the percept and the image seems to us an awkward figure by which to describe the facts. The sequence of states of consciousness in the case of (*a*) practical or perceptual, and (*b*) reflective or conceptual recognition, seems to be briefly as follows. Suppose I recognize a man, A, as one whom I have met before, say at a dinner party. Then I have first a percept $\overset{A}{q\,.\,n\,.\,z\,.\,y}$, where A is the individual in question in the focus of consciousness, and $q\,n\,z\,y$ the "fringe" generated by his present surroundings, more or less out of focus. This percept is immediately followed by the image $\overset{A}{s\,.\,r\,.\,t\,.\,b}$, where A appears amid different surroundings. This constitutes practical or perceptual recognition. In reflective or conceptual recognition there follows an act of introspection (or retrospection), whereby the common central element in the two states of consciousness is explicitly identified. There is no fusion in either case, except in so far as sequent states of consciousness have a central or focal element which is identifiable. If we simply recognize A as someone we have met somewhere, we do not remember where, there is associated with the focal image, A, an indefinite fringe of pastness serving to differentiate it from the percept with its fringe of present surroundings; and if, on the other hand, we recognize A as a quite familiar person whom we have seen again and again amid all sorts of surroundings, there is a fringe which we can only describe as involving both pastness and frequency. In the case of the animal or the child, recognition presumably does not pass beyond the practical stage—that is to say, a percept A with this fringe is followed by an image *A* with that fringe. Reflective recognition, involving retrospection and a comparison of the two images (*A* with this fringe and *A* with that fringe) and the identification of the element common to both, is a product of conceptual processes of later genesis.

In conclusion, it is sufficient to say that by his treatise on the human mind Mr. Sully fully sustains his reputation as a psychologist.

In his volume on "Feeling and Will," Prof. Baldwin has completed the survey of the mind begun in his "Senses and Intellect."

The first three chapters contain an adequate physiological introduction. There is, however, one statement which seems to us awkward if not misleading. After briefly noting the views that have been suggested as to the relation of consciousness to the so-called nervous conditions, Prof. Baldwin says:—

> "It has become apparent that nervous activity, considered by itself alone, does not bring us into the range of psychological science. However we may decide the inquiry as to whether such activity is ever entirely free from consciousness, it is yet true that it may be quite outside of what is called the individual's consciousness. . . . In other words, the greater part of our ordinary nervous reactions are not above the threshold of our conscious lives. So we reach a distinction between sentience as a nervous property and sentience as a conscious phenomenon, between *sentience and sensibility*. Sensibility is synonymous with the usual consciousness of the individual's experience, and sentience is the nervous function which may or may not be accompanied by consciousness or inner aspect in general. . . . The transition from simple sentience to the full consciousness is through a stage of subconscious modification."

With no desire to be hypercritical, this does not seem to us altogether satisfactory. Sentience is spoken of as "the *nervous function* which may or may not be *accompanied by* consciousness." The words we have italicised seem to imply that sentience belongs to the physical, not the psychical order of existence. If so, the "transition from simple sentience to full consciousness" is a transition from the physical to the psychical order, and consciousness becomes a mode of energy. We do not think that this is the author's meaning; but in that case it would be well so to define sentience as to clearly show that though it may not rise to the level of consciousness, it is none the less of the conscious or psychical order.

When we leave the physiological and enter the psychical field, appeal is constantly made to the "principle of apperception" or "selective synthesis." But does not the author go somewhat beyond what is justified by our very imperfect knowledge of the facts of cerebral physiology when he asserts that "after we enter consciousness, we find a principle of apperception to which there is no analogy in physiological integration"? Elsewhere he says: "Now, as a fact, the great principle of mental organization, selective synthesis, finds no apparent counterpart in physics." In direct opposition to this view, we venture to contend that nothing is more remarkable than the parallelism (if it be no more) of selective synthesis in the physical and the psychical spheres. In the physical world this is best seen in the formation of chemical compounds and their segregation in crystalline form. In the psychical world it is seen in the so-called principle of apperception. This is, however, only the expression in the conceptual sphere of a principle which, stripped of all metaphysical implications, must be extended to the whole range of psychical life, as a general law of psychogenesis. In the organic world (at any rate the animal world) the two principles (if two they be) meet. And if, notwithstanding the splendid work done in bionomics, through the application of "natural selection" to the elucidation of the problem, we have not yet reached a scientific expression of selective synthesis in organic life and growth, this is no proof that there is no such selective synthesis.

In accordance with the general principles he adopts, Prof. Baldwin divides feeling into the two great classes of (1) sensuous feeling, and (2) ideal feeling. Sensuous feeling relates to the bodily functions. "Sensuous pleasure," says the author, "may be defined as the conscious effect of that which makes for the continuance of the bodily life or its advancement; and sensuous pain, the conscious effect of that which makes for the decline of the bodily life or its limitation." Ideal feelings, on the other hand, are the modifications of sensibility which accompany the exercise of the apperceptive function. Ideal pleasure may be defined as "the conscious effect of that which makes for the continuance of the apperceptive life or its advancement; and ideal pain, the conscious effect of that which makes for the decline of the apperceptive life or its limitation." But though sensuous feeling can have no reference to the conceptual or apperceptive life, ideal feeling has reference (however much we affect to despise or ignore the mere body) to physical as well as intellectual well-being. Hence Prof. Baldwin concludes "that ideal tone (pleasure or pain) refers to personal well-being as a whole."

We must pass over without comment an important and interesting discussion of "reality and belief," which is worthy of careful consideration, and may proceed to note the somewhat unusual sense in which the author uses the word "ideals."

> "Ideals," he says, "are not mental constructions at all: if once constructed they would no longer be ideals: which only means that what we call ideals are emotional in their nature, expressing the drift or felt outcome of the constructive process, not any actual attainment of it. If my ideal man, for example, were an intellectual construction, I would be able to describe him. . . . Ideals, therefore, are the forms which we feel our conceptions would take if we were able to realize in them a satisfying degree of unity, harmony, significance, and universality."

This seems to us somewhat strained. It is a description of theoretically ideal ideals which have been emptied of all practical value. There are assuredly practical ideals which, though unattainable, can be definitely realized as intellectual constructions permeated with emotional tone. And it is these practical ideals which are influential on conduct.

The distinction between subjective and objective ends in ethics is carefully drawn. Subjective ends are the felt and more or less definitely realized motives of the voluntary process. They alone have psychological value as the immediate determinants of conduct. Objective ends are a matter of cognition.

> "Even though it were granted that all voluntary action arose and survived by exclusive reference to pleasure or to self-realization, yet it would be a patent fallacy to say that the only voluntary end is either of them—that consciousness has all along been versed in our biology or our speculative ethics, and has aimed to fulfil the one or the other. Consciousness has no inkling of the *δύναμις* of Aristotle, or the *connatus* of Spinoza, or the *Trieb* of Wundt and Schneider; of the 'strife [*sic*] for existence' of Spencer, the theoretic 'reverence for law' of Kant, the 'self-realization' of Green, or the dialectical 'becoming' of Hegel. Let us discover these things if we may, but do not let us say that a man is not moral unless he has a realizing sense of them."

We have left ourselves no space to deal with Prof. Baldwin's discussion of the phenomena of the will. We do not by any means agree with all that he says thereon, but it is worthy of careful consideration.

Prof. James's "Text-book of Psychology" is a rearranged abridgment of his larger "Principles," with the addition of some description of the senses and sense-organs. We have so recently (NATURE, vol. xliii. p. 506) expressed our opinion of the value of the larger work, that we can, without injustice to Prof. James, afford to be brief in our notice of this abridgment, merely selecting the chapter on "Instinct" on which to offer a few comments.

Every organism comes into the world with an innate capacity to perform, more or less definitely, certain activities under the appropriate environing circumstances. Of these activities, a certain number which are (1) complex in character, and (2) performed (*a*) in a definite way, (*b*) without foresight of the end to be attained, (*c*) with no previous education in the performance, and (*d*) uniformly by all normal individuals of the species concerned, are now by pretty common consent described as instinctive. Clearly such instinctive actions are the outcome of the innate capacity of the animal which performs them; but they are a peculiar and special manifestation of this innate capacity: they have definite and clearly assignable characteristics. Now no one can question that man comes into the world with a relatively enormous store of innate capacity, and that he has innate tendencies to perform half a hundred particular activities. And yet he has but few instincts. He leads a life of hesitation and choice, an intelligent life. To say with Prof. James that this is "not because he has no instincts—rather because he has so many that they block each other's path"? is practically to abandon the position which has been painfully and slowly gained by those who have thought and written on instinct. Instinct is a definite and special manifestation of innate tendency: here the innate tendency is not manifested in this definite and special way, but is thwarted. To call both manifestation and non-manifestation alike instinct is, in our view, a retrograde step, which we regret that a psychologist of Prof. James's insight and influence should have taken.

We cannot, however, leave the book with a note of dissent; for we find far more in this text-book to agree with than to dissent from. Whether we agree or dissent, we always find Prof. James full of stimulating thought; and we advise all who are interested in psychology to read at least the chapters on "Habit," "The Stream of Consciousness," and "The Self," if they read no more.

C. Ll. M.

DYNAMICS OF ROTATION.

Dynamics of Rotation: an Elementary Introduction to Rigid Dynamics. By A. M. Worthington. Pp. 155. (London: Longmans, Green, and Co., 1892.)

Spinning Tops. By John Perry. Pp. 136. (London: Society for Promoting Christian Knowledge, 1890.)

THE persistence of spinning tops and of running bicycles in rearing themselves erect are common examples of a wide class of dynamical phenomena which are influenced or governed by the presence of rapidly rotating parts, and which have a prominent place in all departments of physical science, from the relations of the systems of the stars down to molecular actions.

In formal treatises on abstract dynamics we are accustomed to find the properties of freely rotating systems relegated to an advanced part of the development of the subject, and expounded with all the powerful help which mathematical analysis can afford. If we are to have a complete theory of the circumstances which determine the stability and transformations of rotational motions, this analytical aid is none too extensive. But there is another mode of approaching a physical subject, which consists in learning from observation and properly varied experiment what are the phenomena that are persistent and stable, and then applying known dynamical principles to the elucidation of the properties of the motions thus known in fact to exist—a problem which need not in those simpler cases which are fundamental require any great amount of analytical knowledge.

As an additional reason for the customary abstract development of dynamics, there may perhaps be counted the historical fact that the questions that were of paramount importance when dynamical principles concerning extended systems of bodies were being evolved, related to the orbital and axial motions of the heavenly bodies, and their reconciliation with the law of universal gravitation. The absence of frictional resistances, and the long duration and delicacy of astronomical observations, had led to a minute knowledge of the motions of the solar system, which taxed all the resources of Clairaut, D'Alembert, Laplace, and Lagrange, to verify and explain.

Many of the dynamical principles which are now treated as elementary and fundamental were thus come upon in special analytical investigations relating to physical astronomy. It was, for example, in this way that the principle of the conservation of angular momentum for the solar system was discovered by Laplace, and then generalized to a system with any kind of internal connections which is not subject to forces from outside it. How far a general principle of this kind, when divested of its analytical dress, enables us to see into the general causes of things is well known. A striking illustration is the *aperçu* of Prof. James Thomson, that when once the trade winds have been explained as a consequence of the earth's rotation, they involve of necessity the existence also of anti-trades or south-west winds in the temperate zone; for if the trades blew by themselves their friction against the earth would always be acting round in the same direction, and therefore would tend to stop the earth's rotation, not by wholly destroying its motion, but by transferring its angular momentum undiminished to the atmosphere, where it would continually accumulate. This simple remark thus shows that the trades blowing to the equator must be compensated by anti-trades blowing from it; and therefore also explains the existence of a region of high barometer between them. It will also occur to memory how much J. Purser, W. Thomson, and specially G. H. Darwin, have established in the tidal evolution of the earth-moon system, by studying the possibilities of development that are allowed subject to the conservation of its angular momentum and the degradation of its energy.

It has been reserved for our own half-century to bring out the wealth of general dynamical ideas that is contained in the magnificent analytical presentation by Lagrange of the results of the application of the laws of motion to systems of bodies, the number of variables or co-ordinates being of necessity (for analytical purposes) restricted to the number of degrees of freedom, and everything turning out to be expressible in terms of one fundamental function—the energy of the system. It will be apparent, on looking through Prof. Cayley's Reports on Dynamics to the British Association, how much the progress of this department of abstract dynamics was indebted to the necessities of astronomy. That science presented a problem which was in one sense quite definite and precise, on account of the smallness of the planetary masses, but which nevertheless required a minute explanation of the perturbations to which the planetary bodies are subjected owing to their mutual actions. The methods which proved comprehensive and efficient for this purpose also showed themselves, when they were examined from a more general standpoint, to reveal principles of a far-reaching character, that applied to dynamical systems however complicated. The final stage of analytical development was reached when the keen perception of Sir W. R. Hamilton saw that the whole subject could be removed from special considerations of space and time, and attached to the purely analytical treatment of a single varying action function; and the commentary of Jacobi showed precisely how to pass from this general differential analysis to the solutions of special dynamical questions.

At the present time there seems to be no danger of the interruption of progress by too close an adherence to the calculus. The fact is, that nearly all the problems of the numerical calculation of perturbations which were urgent at the beginning of the century, in order to bind the solar system to the scheme of universal gravitation, have now been satisfactorily disposed of. There is no longer the same need for the greatest intellectual power to set itself to put right some periodic or secular inequality, which requires all the battery of analysis that is available, and often more. New ground has been broken since then, and there is the great array of the physical sciences, all struggling to become purely dynamical, but all hampered in this by the fact that the dynamical machinery, the phenomena of matter and motion, on which they depend, are to a great extent concealed from direct observation or exploration. Under such circumstances the method of progress is to carefully cherish, and reduce into a scheme such as will appeal directly to the understanding, all the general principles which have become evolved in the course of dynamical investigations relating to problems of which the data are thoroughly known; and to use them as a key for the dynamical interpretation of more recondite phenomena by the aid of analogies and the numerical verification of their results. The mode of progress has thus veered from the analytical to the synthetical, from the powerful inverse analysis of Laplace and Lagrange to methods more akin to those which were worked by Newton.

It may be stated as a general rule that the relations most directly intelligible and most flexible in this kind of application are properties of constancy, or of maximum and minimum, such as belong in fact to the more obvious features of the continuous growth of pure quantity. The conservation of energy, of linear momentum, of angular momentum, the minimum energy criterion of equilibrium, of steady motion, the maximum and minimum energy criteria which determine the motion following the application of impulses specified either by their actual amounts or by the velocities they produce at their points of application—these may all be cited in illustration. The crown of the edifice will be Maupertuis's principle of Least Action, whose range of exact application, initiated for dynamics by Lagrange and Hamilton, is now being extended into all departments of physics, thus working out an answer to the question—To what extent can the succession of phenomena in inanimate Nature from instant to instant be treated as governed by a principle analogous to that of minimum expenditure of effort in the sentient world?

The phrase from instant to instant is essential, for a path may—as, for example, a great circle on a sphere—be the shortest between two points within a given range of each other, but may cease to have that property when the starting point and the final point are taken too far apart on it. In a similar way, in statics, a certain region of stability is determined around each position of equilibrium, such that, if the system is not disturbed beyond that region, it will not leave the neighbourhood; while, in dynamics of a particle, such a region is more vaguely determined around each orbit by the nature of the enveloping curves or surfaces of the neighbouring orbits.

From the point of view of the direct appreciation of dynamical ideas, the small books at the head of this article form a very welcome addition to the ordinary text-books. The work of Prof. Perry, popular lecture though it be—and one feels constrained, from the confident style, to believe that his audience of operatives understood every word of it—leads on the reader by vivid illustration into contact with the boldest flights of dynamical speculation. After the ordinary effects of spin have been copiously illustrated, we are taken into a world in which matter has two kinds of inertia; and, by aid of a chain of balanced gyrostats, we learn that a cord cannot ever transmit motion straight on without also twiddling about. It is fortunate for those of us who have to follow or teach mechanical pursuits that this new species of matter is not often heard of, and is only called up in relation to such unnoticeable, and practically insignificant, phenomena as rotation of the plane of vibration of light waves. The relations of ordinary mass to gravitation, and such like are sometimes intricate enough things to discuss; the introduction of a second kind of mass, and that of a vector character, might lead to despair.

The great pioneer in this field of work, of eliciting the concealed dynamical mechanism of tangible phenomena, is, of course, Lord Kelvin, by whom nearly all our knowledge on the subject has been originated, at any rate in its present exact form. Prof. Perry's book is all the more welcome and suggestive, in that it claims to be chiefly a connected account of what he has learned at first hand from the teaching of Lord Kelvin; an account which has possibly not been published before by anyone, at least in a consecutive form.

Prof. Worthington, after an elementary quantitative introduction to dynamical principles, has gone over the part of dynamics of rotation which relates to a single spinning solid, in the manner of a text-book with numerical illustrations; and there is no doubt that a mastery of his explanations would be a very valuable part of the outfit of a student of physics. J. L.

THE MAMMALIA OF BRITISH INDIA.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Mammalia. Part II. By W. T. Blanford, F.R.S. (London: Taylor and Francis, 1891.)

IN our issue of September 27, 1888, we had the pleasure of bringing before the notice of our readers the first part of Mr. Blanford's valuable monograph on the Mammals of British India. The second part, completing this important work, has lately been published. The delay, as is explained in the preface, has been caused by the necessity Mr. Blanford has been under of spending much time in editing the five volumes of the same series that have appeared since the first part of the present work was issued. His labours in this respect have been increased by two unfortunate and unforeseen circumstances—the lamented death of Mr. Francis Day, and the expiration of the leave of Mr. E. W. Oates, in both cases before the termination of the portions of the work, on fishes and birds respectively, upon which they were engaged, and the completion of which has thus fallen upon Mr. Blanford himself.

In the preface of the present part, the origin of the series to which it belongs is thus related:—

"The need for new and revised descriptive works had, for some years before 1881, been felt and discussed amongst naturalists in India, but the attention of the Government was, I believe, first called to the matter by a memorial dated September 15 of that year, prepared by Mr. P. L. Sclater, the well-known Secretary of the Zoological Society, signed by Mr. Charles Darwin, Sir J. Hooker, Prof. Huxley, Sir J. Lubbock, Prof. W. H. Flower, and by Mr. Sclater himself, and presented to the Secretary of State for India. This memorial recommended the preparation of a series of hand-books of Indian zoology, and my appointment as editor. It is scarcely necessary to add that to the recommendation of men so highly respected and well known in the world of science, the publication of the present 'Fauna of British India' is greatly due, and that Mr. Sclater is entitled to the thanks of all interested in the zoology of India for the important part he took in the transaction."

We are also glad to learn from the same source that the series of works on the fauna of British India will not be confined to the Vertebrata, the preparation of three volumes on Moths by Mr. G. F. Hampson having been commenced. We trust that these will be followed by others dealing with those groups of which sufficient material is available, and for which authors may be forthcoming capable of treating them in a manner worthy to be placed by the side of those already issued.

The second part of the Mammalia contains the orders Chiroptera, Rodentia, Ungulata, Cetacea, Sirenia, and Edentata. It is fully equal to its predecessor in careful selection of the material which is most likely to be useful and attractive to those readers for whom the work is chiefly intended. The descriptions, geographical distribution, and accounts of the habits of the various species can be thoroughly relied upon. Nomenclature is always a thorny subject in zoology, and though Mr. Blanford is usually most careful and judicious in his work in this department, we cannot agree with him in substituting the specific name of *maximus* for the time-honoured and universally used *Elephas indicus*. The inconvenience of changing the name by which such a familiar animal is designated in thousands of books and museums, is so great that it can only be justified by some more imperious necessity than appears to exist in the present case. That *maximus* was applied by Linnæus to both the then known species, and that it is incorrect and misleading (the other existing, and many of the extinct, species being as large as, or larger than, the Indian elephant) are sufficient reasons, in our judgment, for leaving the name in the oblivion in which it has slept for nearly a century. Moreover, if *indicus* be rejected, the claims of Blumenbach's *asiaticus* cannot be overlooked.

The illustrations of the present part are far superior to those of the former one, and show a marked advance in the art of process-printing directly from the artists' drawings, without the intervention of the wood-cutter. Many of those by Mr. P. Smit, though printed from blocks in the text, have all the softness and delicacy of the finest specimens of lithography, and add greatly to the attractiveness of this valuable work.

W. H. F.

OUR BOOK SHELF.

Tanganyika: Eleven Years in Central Africa. By Edward Coode Hore, Master Mariner. (London: Edward Stanford, 1892.)

MR. HORE was for eleven years a member of the Central African Mission established at Lake Tanganyika by the London Missionary Society, his special task being to undertake all the work that could be most effectually accomplished by one who had the knowledge and experience of a master mariner. In the present book he gives an account of his labours. The narrative contains many elements of interest, and will be read with pleasure by all who like to think of devoted courage in the service of great moral ideas. Mr. Hore became very familiar with Lake Tanganyika, which he surveyed in the first instance on board a native boat. Afterwards the British supporters of the mission enabled him to build two vessels in which he had opportunities of doing his work in a style worthy of its magnitude and importance. Of the physical characteristics of the lake and the surrounding regions he gives an unpretending but sound and sometimes picturesque account. He has also much to say about the natives, whose confidence and good-will he seems to have had a rare power of winning. He has a very favourable opinion of their capacities, and knows of no good reason why they should ever be treated by Europeans otherwise than with kindness and patience.

Beginner's Guide to Photography. By a Fellow of the Chemical Society. (London: Perken, Son, and Rayment, 1892.)

THIS very cheap and useful little guide has now reached its fourth edition. The reader is led through all the phases of manipulation that at first sight seem so bewildering, but which with clear explanations are soon rendered more simple and eventually mastered. All questions relating to "How to buy a Camera, and how to use it," may be said to be here fully answered, and by following the instructions an amateur may be saved from much disappointment and expense. The explanations throughout the book are both clear and explicit, and the omission of such technicalities as might confuse rather than enlighten a reader will be found distinctly advantageous.

Quain's Elements of Anatomy. Edited by E. A. Schäfer, F.R.S., and G. D. Thane. In Three Vols. Vol. II., Part 2. By Prof. Thane. Tenth Edition. (London: Longmans, Green, and Co., 1892.)

IT is necessary here only to record the fact that the publishers have issued the second part of the second volume of this magnificent edition of Quain's standard work. The editor is Prof. Thane, and the subjects dealt with are arthrology, myology, and angeiology. There are no fewer than 255 illustrations, many of which are coloured.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Zebra's Stripes.

ALMOST every writer who treats of the colours of animals refers to Galton's observations that in the bright starlight of an African night zebras are practically invisible even at a short distance; but there can be no doubt that their peculiar striped appearance is also of great protective value in broad daylight. On a recent zebra hunt near Cradock, in which I took part, several members of our party commented on the difficulties of seeing zebras even at moderate distances, although there was nothing to hide them, the black and white stripes blending so completely that the animals assume a dull brown appearance quite in harmony with the general colour of the locality in which they are found, and in which, for instance, Rooi Rehbok (*Pelea capreolata*) is also well protected on account of its peculiar brownish coat. A member of our party, who on another occasion gave proof that he is possessed of excellent eyesight, and who has frequently hunted in similar localities, saw a zebra which was wounded in one of the front legs at a distance of about 400 yards, and strange to say he mistook it for a big baboon. In a letter which I received from him a few days ago, he said, "It galloped like a baboon from me, and I could only see that the colour was greyish-brown. At about 500 yards from me it ran on to a little krantz, and mounting the highest rock, drew its body together just as a baboon does when its four feet are all together on the summit of a little rock." His remark as to the greyish-brown colour of the animal is the more valuable, as I believe this gentleman, Mr. Wrench, A.R.M. of Cradock, is quite unprejudiced. In my own letter to him, which drew forth these remarks, I had only asked him for the distance at which he saw the zebra, and I did not ask him how it was that he mistook a black and white zebra for a brown baboon on a perfectly clear South African day. My own observations also confirm that the stripes of the zebra are of protective value. Riding along a slope I suddenly saw four zebras within 100 yards above me. They were galloping down the hill, but stopped when they caught sight of me. As soon as they stopped I saw their stripes pretty distinctly. After I had fired and wounded one of them, they started again galloping down the hill round me in a semicircle at a distance of about 70 yards. All this time they presented a dull brown appearance, no stripes being visible, although I had my attention fixed on this point. They disappeared beyond a ridge, went down a little valley, and I heard afterwards that they ascended the next slope, which was not more than 1500 yards away from where I stood with a native servant. Yet even this lynx-eyed native could not see them going up this slope. They had vanished from us.

Perhaps it may interest some of your readers that zebras are still fairly plentiful on the rugged hills west of Cradock. A troop of forty-one individuals was seen, on the very ground over which we hunted, a short time before we arrived. Our party saw eleven in two days, but I believe three were seen on two if not on three different occasions. This would reduce their number to eight, if not to five. They are protected by Government, and also by the farmers themselves, but I am afraid that in spite of that their days are numbered. They are said to be very destructive to wire fences, and as the inclosing of farms with wire fences is steadily on the increase in this colony, many a farmer will have, though perhaps reluctantly and in defiance of the law, to take up his gun and clear them off his property. There will then probably be an outcry by people who know the difficulties of South African farming only from books written by travellers who hurry through South Africa in a first-class railway carriage; but those who really know South Africa well will say it is a great, great pity, but it cannot be helped, unless Government provides speedily an abode for these and other animals threatened with extinction. The first step in the right direction would perhaps be the establishment of a Government Zoological Garden, but I hope others who are more competent than I am will stir the people of Cape Colony up before it is too late, so that something more than mere game-laws may be done to preserve them.

S. SCHÖNLAND.

Albany Museum, Grahamstown.

The Protective Device of an Annelid.

IN September last I forwarded to NATURE the description of an effectual protective device adopted by a small tubicolous Annelid which had been sent to me from Jersey; the device consisting in the coiling-up of the end of the tube. I have recently been able to submit specimens to Prof. W. C. McIntosh, of St. Andrews, who has kindly identified the builder as *Sabella saxicava*, a form which he tells me is common in the Channel Islands, and occurs also on our southern coast. So far as I can learn, this peculiar and interesting habit of an Annelid had not previously been observed.

ARNOLD T. WATSON.

Sheffield, May 1892.

The General Circulation of the Atmosphere.

IN that excellent lecture by Dr. Pernter, delivered before the Scientific Club at Vienna, published by you in NATURE (vol. xlv. p. 593), the theory of the trade winds being occasioned by the rising of the rarefied air at the equator causing an upward current, while cold air from north and south flows in to supply its place, coupled with the earth's rotation to the east, is attributed to Dr. Dove. "Dove was the first person . . ." But that theory will be found distinctly enunciated by Sir John Herschel in his "Treatise on Astronomy" (1833), where he attributes it to Captain Basil Hall, "where this is distinctly, and, as far as I am aware, for the first time reasoned out." Herschel was not aware that it had been distinctly reasoned out by George Hadley, F.R.S., in the thirty-ninth volume of the Philosophical Transactions, a century before Basil Hall.

J. CARRICK MOORE.

THE SURFACE-FILM OF WATER, AND ITS RELATION TO THE LIFE OF PLANTS AND ANIMALS.[1]

IT is necessary to the exposition of my subject that I should begin by reminding you of some well-known properties of the surface of water. These are familiar to every student of physics, and are set forth in many elementary books. They are well explained and illustrated, for instance, in Prof. Boys's deservedly popular book on "Soap-bubbles." But there may be some persons here who have not quite recently given their thoughts to this subject, and it will only cost us a few minutes to repeat a few simple experiments, which will establish some fundamental facts relating to the surface-film of water.

The following experiments were then shown:—

(1) Mensbrugghe's float. Proves that the surface-film of water offers resistance to the passage of a solid body from beneath.

(2) Aluminium wire made to float on water. Proves that the surface-film of water offers resistance to the passage of a solid body from above. The resistance is proportional to the length of the line of contact of the solid with the water.

(3) Copper gauze made to float on water. Here, a number of intersecting wires are employed instead of a single wire, and the consequent increase in the length of the line of contact greatly increases the weight which can be supported.

(4) Frame with vertical threads, carrying a light plate of brass. The threads hang vertically at first, but when the whole is dipped into soapy water, the adhering film exerts a pull upon the sides of the frame, draws the threads into regular curves, and raises the brass plate. When the film is broken, the threads resume their previous vertical position, and the plate falls.

(5) Aluminium wire supported by vertical copper wires. Each end of the aluminium wire forms a loop, which fits loosely to one of the copper wires. When the apparatus is dipped into soapy water, the contraction of the film draws the aluminium wire upwards. After pulling it down with a thread, the wire can be again drawn up. This is another illustration of the tendency of the film to contract. We use soapy water, because the film lasts for a considerable time, but the surface-film of pure water, though less viscous than that of soapy water, is even more contractile. We have already seen that the surface-film clings with considerable tenacity to any solid body introduced into it, and that its hold increases with the length of the line of contact. It is for this reason that fine meshes offer so great a resistance to the passage of the surface-film. Air can pass through the meshes with perfect ease; water also, if not at the surface, can pass through readily enough, but the surface-film in contact with air will only pass through with

---

[1] Lecture given at the Royal Institution, March 4, 1892, by L. C. Miall, Professor of Biology at the Yorkshire College, Leeds. Some passages were omitted in delivery, for want of time.

difficulty, and if there is water behind it, the water may thus be restrained from passing through the meshes.

(6) Muslin bag hung in front of the lantern. Water poured into the bag (a large spoonful) does not flow out; but when the muslin beneath the water is rubbed with a rod, it becomes wetted, the surface-film passes to the outside of the bag, and the water trickles through.

There are many plants which take advantage of this property of the surface-film of water, viz. that it will not penetrate small spaces, in order to keep themselves dry. You must have observed how the hairy grasses repel water. The surface-film is unable to pass into the fine space between the hairs, and accordingly the water above the surface-film is kept from contact with the leaf. This simple artifice is often employed by plants which float at the surface of water. Here it is important that they should keep dry, not only for the purpose of respiration, but for another reason too. They commonly have great power of righting themselves when accidentally submerged, and this self-righting property depends upon the fact that the under surface of each leaf is always wet, while the upper surface is incapable of being wetted.

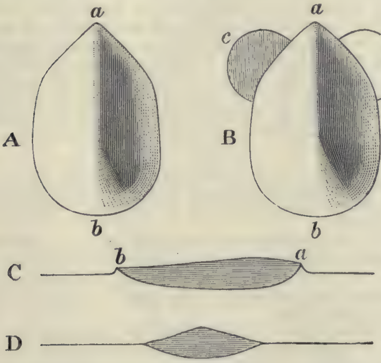

Fig. 1.—Duckweed (*Lemna minor*), magnified. A, single frond; *a*, scar of attachment to parent. A ridge extends from *a* to *b* across the upper surface of the frond, gently subsiding towards *b*. B, frond, budding-out two new fronds. C, longitudinal section from *a* to *b* (A), showing ascending capillary curves at *a* and *b*. D, transverse section, at right angles to the last. The margins of the frond in this plane are level with the surface of the water. N.B. The form of the fronds is somewhat variable. Minor inequalities occur along the margin, but the principal ascending curves, which are also centres of attraction, are at *a*, *b*, and *c*.

The microscopic hairs which thickly cover the upper surface are sufficient to exclude the water. A leaf of Pistia is now submerged, and shown as an opaque object in the lantern. You see by the gleaming of its surface that it is overspread by a continuous flat bubble of air, which looks like quicksilver beneath the water. I will next invert a leaf of Pistia by means of a rotating lever. It is now brought up beneath the surface of the water in an inverted position, and you see that, notwithstanding its buoyancy, it is unable to free itself and rise to the surface, because of the air-bubble, which adheres both to the leaf and to the disk at the end of the lever, and ties both together. Complete separation of the leaf from the disk would involve the division of the air-bubble into two smaller bubbles, one adhering to the leaf and the other to the disk. In this operation the surface-film would necessarily be extended directly in opposition to its natural tendency to contract. Several other water-plants exhibit the same properties as Pistia. I will mention two of the water-ferns—Salvinia and Azolla. Salvinia is found floating on still water in the warmer parts of Europe, as well as in other quarters of the globe. The leaves are attached on opposite sides of a horizontal stem. Long hairy roots (or what look like roots, and really answer the same purpose) hang down into the water. Salvinia has in a remarkable degree the power of rising when submerged, of always rising with its leaves up and its roots down, and of rising with the upper surface of its leaves perfectly dry. It is obvious that these qualities are most useful to a plant which may be pressed under water or drenched with rain. Its nutrition, like that of all green plants, depends largely upon substances extracted from the air; and to be overspread with water, which disappeared only by a slow process of evaporation, would be disadvantageous, especially if the water were not absolutely clean. Every leaf of Salvinia is, to begin with, excavated by a double layer of air-spaces, which lodge so much air as to give it great buoyancy. On the upper surface are placed at regular distances a number of prominences, each surmounted by a group of about four stiff, spreading hairs, which keep the water from reaching the surface of the leaf. When forcibly depressed, the Salvinia takes down with it a layer of air, which forms a flat bubble over the leaf, and of course gives great power of self-righting, for the specific gravity of the upper

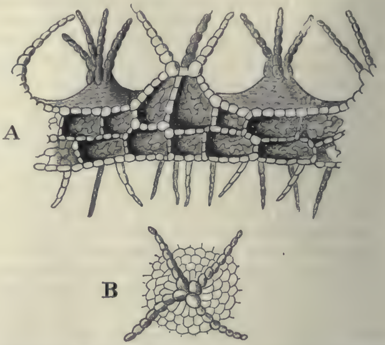

Fig. 2.—*Salvinia natans.* A, combined surface-view and section of floating leaf, modified from a figure in Sachs's "Botany," showing the air-cavities, the submerged hairs of the lower surface, and the groups of stiff hairs on the upper surface. These latter inclose spaces into which water cannot enter, even when the leaf is completely submerged. B, one group of hairs from the upper surface, seen from above.

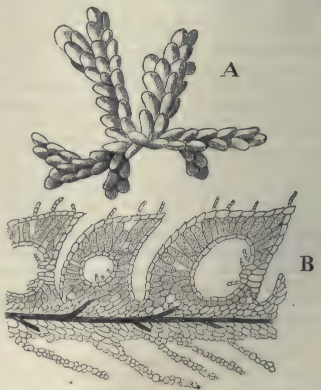

Fig. 3.—*Azolla caroliniana.* A, stem with leaves, magnified; B, longitudinal section through part of ditto, highly magnified. The air-cavities of the leaves are shown, the narrow spaces between the leaves, into which water cannot enter, the fine hairs of the upper surface, the submerged leaf-lobes, and the vascular bundles.

side is greatly reduced, while the lower side is weighted, as before, by the long, water-logged roots. Once restored to the surface, the bubble bursts, and the little drops into which it is instantly resolved roll off like drops of quicksilver. Azolla, which is found in most hot countries, and is often grown in hothouses, behaves in a very similar way. Here the leaves are far smaller, and crowded together upon a branching stem of minute size. There are a few hairs upon the upper surface, and between the leaves are narrow clefts, connected with globular cavities, which occupy the centre of every leaf. These cavities, which are often closed, and never possess more than an outlet of extreme minuteness, are always filled with air; so are the clefts between the leaves. No water can lodge on the upper surface, apparently because the surface-film is stretched from the raised edge of one leaf to that of the next; and thus buoyancy, self-righting, and repulsion of water are efficiently secured.

Many plants which ordinarily float on the surface of the water (Salvinia, Azolla, Duckweed, *Potamogeton natans*, &c.) sink on the approach of winter. At this time it is very curious to see how completely they lose both their buoyancy and their power of repelling water. I do not know how this change is brought about, but the result is one of obvious advantage. The leaves, or in some cases the entire plants, sink to the bottom, and hibernate there, out of the reach of frost. Many perish; some are broken up by decay into isolated buds. When spring returns, the few survivors float up, and soon cover the surface with leaves. It would be interesting to know something of the mechanism by which these seasonal changes are effected.

One of the commonest objects in Nature, which is apt to escape our notice on account of its minute size, for it is less than one-quarter of an inch in length, is the egg-raft of the gnat. This was beautifully described 150 years ago by Réaumur. The eggs of the gnat are cigar-shaped, and 250 or 300 of them are glued together, so as to make a little concave float, shaped like a shallow boat. The upper end of each egg is pointed; the lower end is provided with a lid, through which the larva will ultimately issue into the water. The gnat in all stages, even while still in the egg, requires an ample supply of air. It is therefore necessary that the egg-raft should float at the surface; it is also necessary that it should always float in the same position, so as to facilitate the escape of the larva. This is effectually secured by a provision of almost amusing simplicity. Let us first notice how efficient it is. If we take two or three of these tiny egg rafts, and place them in a jug of water, we may pour the water into a basin again and again; every time the egg-rafts float instantly to the surface; and the moment they come to the top, they are seen to be as dry as at first. The fact is that the surface-film cannot penetrate the fine spaces between the pointed ends of the eggs. The cavity of the egg-raft is thus overspread by an air-bubble, which breaks the instant it comes to the top. The larva of the gnat, when it escapes from the egg, floats at the surface, and it is enabled to do so in consequence of the properties of the surface-film. When the larva changes to a pupa it becomes buoyant, and floats at the surface, except when alarmed. To enable it to free itself without unnecessary effort from the surface of the water, the respiratory tubes of the pupa are furnished with a valvular apparatus, which can cut the connection with the air in a moment, and restore it at pleasure, when the pupa again floats to the surface.[1]

Another Dipterous insect, whose larva inhabits rapid streams, makes an ingenious use of the properties of the surface-film. This is the larva of Simulium, of which I have given some account in the lecture just quoted. At the time of the delivery of that lecture, I was wholly unable to explain how one difficulty in the life of the insect is surmounted. The larva clings to the water-weeds found in brisk and lively streams. The pupal stage is passed in the same situation. But a time comes when the fly has to emerge. Now the fly is a delicate and minute insect, with gauzy wings. How does it escape from the rushing water into the air above, where the remainder of its life has to be passed? This was a question upon which I had spent much thought, but in vain. It appeared to me for many months completely insoluble. However, I was informed last year by Baron Osten Sacken of a paper written by Verdat, seventy years ago, in which the emergence of the fly of Simulium is described. Guided by Verdat's description, I had little difficulty in seeing for myself how the difficulty is actually overcome. During the latter part of the pupal stage, the pupa-case becomes inflated with air, which is extracted from the water, and passed through the spiracles of the fly into the space immediately within the pupal skin. The pupal skin thus becomes distended with air, and assumes a more rounded shape in consequence. At length it splits along the back, in the way usual among insects, and there emerges a small bubble of air, which rises quickly to the surface of the water and there bursts. When the bubble bursts, out comes the fly. It spreads its hairy legs, and runs upon the surface of the water to find some solid support up which it can climb. As soon as its wings are dry, it flies to the trees or bushes overhanging the stream.

A very interesting inhabitant of the waters, which makes use of the properties of the surface-film to construct for itself a home beneath the surface, is the water-spider (*Argyroneta aquatica*). This interesting little animal has been described by many naturalists, some of whom, judging from their accounts, had no personal acquaintance with its habits. But among the number is the eminent naturalist Félix Plateau, son of the physicist to whom we are so much indebted for our knowledge of the phenomena of surface-tension. I need hardly say that in his account of the water spider, Prof. Plateau gives a full and adequate account of the scientific principles concerned in the formation of its crystalline home.[1] Plateau remarks that the water-spider, like most other spiders, is an air-breathing animal. It dives below the surface, and spends nearly its whole life submerged. In order to do this without interruption to its breathing, the spider carries down a bubble of air, which overspreads the whole abdomen as well as the under side of the thorax. These parts of the body are covered with branched hairs, so fine and close that the surface-film of water cannot pass between them. The spider swims on its back, and the air lodges in the neighbourhood of the respiratory openings, which are placed on that surface which floats uppermost. When the spider comes to the top, as it does from time to time to renew its supply of air, it pushes the abdomen out of the water, and we can then see that this part of the body is completely dry. When it sinks, the water closes in again at a little distance from the body, and the bubble forms once more.

It would be inconvenient to the water-spider to be obliged to come frequently to the surface for the purpose of breathing. A predatory animal on the watch for its victims must lie in ambush close to the spot where they are expected to appear, and the water-spider accordingly requires a lurking-place filled with air, beneath the surface of the water. It has its own way of supplying this want. Relying on the fact, already illustrated by our muslin bag, that the surface-film of water will not readily pass through small openings, the spider proceeds as follows. It begins by drawing together some water-weeds with a few threads, in such a way that they meet at one or more points. It then fetches from the surface a fresh supply of air, and squeezes part of it out by pressing together the bases of its last pair of legs. The bubble rises, but is detained by some of the threads previously spun across its path. Then the spider returns to the surface to fetch another bubble, and repeats the operation as often as is necessary. Now and then she secures the growing bubble by additional threads, and before long has a bubble nearly as big as a walnut, inclosed within an invisible silken net, which imprisons the air as effectually as a dome of glass would do. The spider takes care to conceal her home from observation, and before long the minute Algæ, growing all the more vigorously because of the air brought to them, effectually conceal the habitation. The mouth of the dome, which is of course beneath, is narrowed to a small circle, and Plateau has observed a cylindrical horizontal tube, seven to eight millimetres in diameter, by which the spider is enabled to enter or leave her home without being observed. The air within is renewed as required, by the visits of the spider to the surface.

---

[1] The larva and pupa of the gnat are more fully described in my British Association lecture on "Some Difficulties in the Life of Aquatic Insects," reported in NATURE, vol. xliv. p. 457.

[1] "Observations sur l'Argyronète aquatique," *Bull. Acad. Roy. de Belgique*, 2me. sér., tom. xxiii., 1867.

Besides this home, which is the ordinary lurking-place of the spider, another is required at the time when the young are hatched. The new-born spiders are devoid of the velvety covering of hairs, and would drown in a moment if placed in a nursery with a watery floor. The female spider therefore makes a special nest for this particular occasion, which floats on the surface of the water, rising well above it. It is bell-shaped and strongly constructed. The upper part is partitioned off, and contains the eggs. Beneath the floor of the nursery the mother takes her station, and watches over the safety of her brood, defending them against the predatory insects which abound in fresh waters. It is interesting to see how the faculty of spinning silk, used by the house-spider for her snares, and at other times for the fluffy cocoon in which the eggs are enveloped, furnishes to the water-spider the materials of her architecture. It is not less interesting to observe the economy of material which results from the use of the tenacious and contractile surface-film, in place of a solid wall.

We will next consider another property of the surface-film, which is turned to account in the daily life of the very commonest of our floating plants, I mean the duckweed, which overspreads every pond and ditch. A number of the green floating leaves of duckweed are now placed in a shallow dish in the field of the lantern, and I will ask you to observe how they are grouped. They have spontaneously arranged themselves in a very irregular fashion, forming strings and chains which spread hither and thither over the surface of the water. This is not the way in which most floating bodies behave. Let us remove the duckweed, and replace it by another dish of water in which I will put a number of small disks of cork.[1] You will see that the bits of cork are attracted one to another and crowd together in one place. Let us inquire why the floating bits of cork are thus attracted towards one another. If any solid capable of being wetted by water is partly immersed in water, the liquid rises round it in an ascending capillary curve. If the solid is not wetted by water, the curve will turn downwards. We may get ascending or descending capillary curves in other ways. If, for instance, I were to lay a sheet of paper upon water, and turn its edges up at certain places, we should get marked ascending curves at these points. The raising of some parts of the surface causes other parts to sink, and may bring about descending curves, or make previously formed descending curves more marked. We shall find it helpful in our experiments to notice one very simple plan of producing a descending capillary curve round the edge of a vessel. If we take a glass of water, and fill it until the water is level with the brim, we naturally speak of the glass as *full*; but if we are careful to avoid rude shaking, we may still add a considerable quantity of water without spilling any. The glass will then become what we may call *over-full*, and its surface will be bounded by a descending capillary curve. Now, it is of immediate importance to us to observe that *like* capillary curves, whether ascending or descending, attract one another, and that *unlike* curves repel one another. The theoretical explanation of this point is not difficult, but it must not detain us here. To place the fact itself beyond dispute, we will try a little experiment. A circular dish of water is now placed in the field of the lantern, and we will introduce into it a small disk of wood. Both the disk and the side of the vessel are wetted by water, and an ascending capillary curve rises round each. The result is that the two bodies attract one another. Every time the disk is moved away it is powerfully drawn towards the side of the vessel. With a little syringe we will add water to the dish in sufficient quantity to raise the level above the edge of the vessel. You will observe that the wooden disk is now repelled by the edge of the vessel, and floats free in the centre. By sucking up a little water, it becomes attracted once more, and so we may go on, causing it to be attracted or repelled, according as we add or subtract a small quantity of water. But what has all this to do with the duckweed? In order to explain the behaviour of duckweed, I must ask you to examine a careful representation of its form. This common plant has not, to my knowledge, been faithfully represented in any botanical book. You will see that the leaf is of an irregular oval shape, broader at one end than at the other, and that the narrow end is pointed. A raised ridge extends along the length of the leaf, from the point to the middle of the opposite or rounded border. Duckweed almost invariably propagates itself by budding. New leaves are pushed out symmetrically on each side of the point. They grow bigger and bigger, and gradually free themselves. The point upon each leaf marks the place where it was last attached to the parent leaf. Sometimes the budding is so rapid, that, before a fresh pair of leaves have become free, they have already budded out a second pair, which we may call the granddaughters of the parent leaf. The pointed end of the leaf, and also the opposite end of the ridge, are raised above the general level, and very marked capillary curves ascend from the general water-level to these points. The free edge of every bud is also raised above the general water-level, and a capillary curve ascends to meet it. Hence, when a number of leaves of duckweed are floating freely on water, they are powerfully attracted one to another at certain points, while at intervening points they are relatively inert. If you take a floating leaf of duckweed, and bring near it a clean needle or a pencil-point, or any similar object, provided that it is not greasy, you will see that the leaf is at once attracted towards the point, but it always turns itself so as to bring one of its ascending curves round to the needle or pencil. We all see in the lantern how readily a leaf of duckweed is made to rotate rapidly by causing a needle-point to revolve round it, without ever touching it. Let us now try to imitate the behaviour of the leaves by some rude models. I have here some elliptical paper floats, cut out with a pair of scissors, and having each of the pointed ends a little turned up. We place these one by one on the surface of the water, and you see in the lantern how they are attracted to one another, point to point, and how they form long chains, which have a tendency to break up into stars. It is the existence of such points of attraction on the margin of the leaves which causes the duckweed to form chains and strings, so long as there is any unoccupied surface in the pond. A moment's consideration shows how profitable this tendency is to the plant. Were the duckweed to crowd together like the floating bits of cork, the pressure towards the centre of any considerable mass of plants would be so great that the new leaves budded out would find no room in which to expand; but, by virtue of one very simple provision, viz. the existence of inequalities of level along the edges of the leaves, clear spaces and lanes are left between the floating leaves, so long as any unoccupied space remains.

---

[1] In order to avoid the inconvenience caused by the attraction of the sides of the vessel, the dish should be over-full of water.

Long exposure to the air, especially in still weather, affects the life of duckweed in a material way. Dust and decaying organic substances give rise to a pellicle, which is most mischievous to floating plants; and I think I could show, if time allowed, how much the habits of duckweed have been altered thereby. But, apart from visible impurities, mere exposure to air gives, as Lord Rayleigh has taught us, a considerable degree of superficial viscosity to water. Hence, the leaves of duckweed, when the surface is contaminated, will tend to lie in whatever positions they may be thrown by accidental causes, such as wind, and the attractions due to capillarity will be more or less impeded. But the effect of the superficial viscosity will in time be overcome by the attractive forces, so that it probably does not in the long run greatly affect the distribution of the leaves over the surface of water.

Many other floating plants, but not all, behave more or less like duckweed, and for the same reason. As yet I know of none which space themselves quite so effectually, and the extreme abundance of the common duckweed, as well as its world-wide distribution, may be partly due to the completeness of its adaptation to capillary forces. Some dead objects may accidentally take a shape which causes them to spread out over water, but I have met with none which have particularly struck me. Floating natural objects, such as sticks or seeds, behave, in many cases at least, very differently, and become densely massed. My attention was first called to this subject by seeing how different was the grouping of duckweed from that of some seeds of *Potamogeton natans*, which were floating in the same pond.

The capillary forces which spread the leaves of duckweed or Azolla upon the surface of water are indirectly concerned in the transport of these and like plants to fresh sites. If we put a stick into water overspread with duckweed, we cannot fail to notice how the leaves cling to the stick. They cling in a particular way, which enables them to bear transport more safely. The wetted surface, for obvious physical reasons, is attracted to the wetted stick; and the water-repellent surface, which is that which best resists drying, is outwards. The tenacity with which duckweed clings to the legs of water-birds, and the position which it almost inevitably takes under such circumstances, may have a good deal to do with the safe transport of the plant to distant pools. It is not, I think, too much to say that the prosperity of duckweed depends very largely upon the capillary forces which come into play at the surface of water.

We have now exhausted our time, though I have been obliged to leave unnoticed many special adaptations of living things to the peculiar conditions which obtain on the surface of water. Had time allowed, I should have been glad to say something about the aquatic animals which creep on the surface-film as on a ceiling, and about the insects which run and even leap upon the surface-film without wetting their minute and hairy bodies.[1] All small animals and plants which float on water necessarily come into contact with the surface-film, and have to deal with the difficulties which result from it. We have seen that they generally manage in the long run to convert these natural difficulties into positive advantages.

I have to thank my colleague, Dr. Stroud, for his frequent explanations of the physical principles upon which these adaptations depend, and also for much practical and valuable help in the preparation of suitable experiments.

---

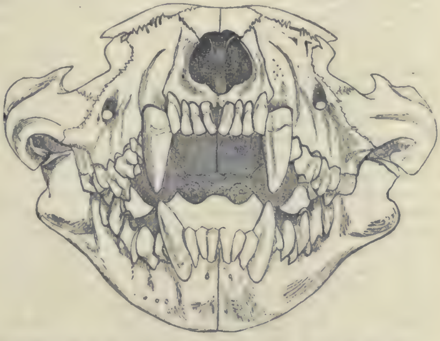
THE DISCOVERY OF AUSTRALIAN-LIKE MAMMALS IN SOUTH AMERICA.

THE year 1891 proved a notable one in regard to marsupials. The existing mole-like marsupial (*Notoryctes*) from the deserts of Central Australia having been made known to us, news came of the discovery in the Tertiaries of Patagonia of remains of carnivorous marsupials closely allied to the existing pouched wolf, or Thylacine, of Tasmania. This discovery was immediately recognized as one likely to considerably modify some of our views regarding the distribution of mammals. A preliminary account of these new marsupials was given by Dr. Florentino Ameghino in a paper written for the new serial, *Revist. Argent. Hist. Nat.* This description seems to leave no doubt as to the correctness of the diagnosis of the fossil remains.

Before going further, it may be well to remind our readers that, with the single exception of the opossums (*Didelphyidæ*) of America, all marsupials are now exclusively Australasian. The carnivorous types, such as the Thylacine (*Thylacinus*) and the Tasmanian Devil (*Sarcophilus*), are distinguished from all living mammals in that their upper cutting-teeth (incisors) are either four or five in number on either side, while in the lower jaw there are invariably three. This relation is shown in the figure of the skull of the Tasmanian Devil—a near ally of the Thylacine—where, between the large tusks of the upper jaw, we see the four pairs of incisors opposed to only three pairs in the lower jaw. In ordinary mammals, on the other hand, the number of pairs of incisors in each jaw does not exceed three, the number of those in the two jaws being usually equal. A further peculiarity of marsupials is that the cheek or grinding teeth comprise four true molars and not more than three premolars; whereas in ordinary mammals the typical number is three molars and four premolars, there being no known instance of the presence of four true molars except in some individuals of the fox-like *Otocyon*. Another peculiarity of most marsupials is the distinct inflection of the lower posterior extremity, or "angle," of the lower jaw, while very frequently the bony palate of the skull has unossified spaces.



Front view of the skull of the Tasmanian Devil. (After Flower.)

The new forms described by Dr. Ameghino were obtained from the lower part of that great series of freshwater formations with which so large an area of South America is covered. It has been inferred that the Patagonian deposits in question are as old as the Lower Eocene of Europe; but, although they are undoubtedly of considerable age, this inference can scarcely be regarded as an established fact, since the occurrence of mammals allied to those of the European Lower Eocene is quite capable of explanation by their survival to a later period in South America.

One of the new Patagonian forms, to which Dr. Ameghino applies the name *Prothylacinus*, is stated to be an animal of the general conformation of the Thylacine, having apparently the same number of teeth, although the upper incisors are unknown. The main distinction of the fossil genus is, indeed, said to consist merely in the circumstance that the lower premolars are more widely separated from one another; the molars of the two forms being described as absolutely identical in character. The fossil likewise exhibits the marsupial inflection of the angle of the lower jaw. The absence of the upper incisors in the specimens of *Prothylacinus* is fortunately compensated in another genus described under the uncouth name of *Protoproviverra*. Here we find that the number of teeth is exactly the same as in the Thylacine, there being four upper and three lower incisors, a canine, three premolars, and four molars on each side of the skull. This dentition agrees numerically with that of the Tasmanian Devil; with the exception that there is an additional premolar in each jaw. These fossils also exhibit the inflection of the angle of the mandible, and the presence of unossified vacuities in the palate, which we have seen to be marsupial features.

As might have been expected to be the case, Dr. Ameghino also states that there appears to be a complete passage from these marsupial forms to others belonging to that group of primitive carnivores known as Creodonts, of which the European Upper Eocene *Hyænodon* and *Pterodon* are well-known examples. Now, if we are to trust these descriptions (and there appears every reason why we should), we must admit that *Prothylacinus* and *Protoproviverra* are veritable marsupials of an Australian type. Then comes the question, How are we to explain the occurrence of such closely allied forms in areas so remote from one another as Patagonia and Australia?

It had long ago been urged that the occurrence of carnivorous marsupials in South America and Australia and nowhere else (at the present time) indicated a former connection between those two areas. To this, however, Mr. Wallace ("Distribution of Animals," vol. i. p. 399) objected that the American opossums (*Didelphyidæ*) were not an Australian type, and that they occurred in the Tertiaries of Europe; and hence he argued that both the American and Australian marsupials probably took their origin from the presumed marsupials of the European Jurassic rocks. This explanation, on Mr. Wallace's own showing, will not, however, hold good for the close resemblance stated to exist between the American *Prothylacinus* and the Tasmanian Thylacine, since it is quite impossible to believe that two such similar forms could have maintained their likeness in such remote regions after having diverged from a common European ancestor as far back as the Jurassic period.

It has, however, been long known that there are certain very remarkable relationships between the fauna and flora of all the great southern continents. For instance, among mammals, the rodent family *Octodontidæ* is peculiar to South (including Central) America and Ethiopian Africa. Then, again, among fishes, the family of the *Chromidæ* is confined to the rivers of South America and Africa, with one outlying genus in India; while the true mud-fishes (*Lepidosiren* and *Protopterus*) are solely South American and Ethiopian, the third representative of the same family being the Baramunda (*Neoceratodus*) of Queensland. Again, the connection between the flora of Africa and that of Western Australia is so intimate as to have induced Mr. Wallace (*op. cit.*, p. 287) to express his belief that there must have been some kind of land connection, although not necessarily a continuous one, between these two widely distant areas. The connection between the fauna of India and that of Ethiopian Africa is now too well known to stand in need of comment. The matter does not, however, end here; for if we go back to the Mesozoic epoch there are equally striking evidences of the connection between the faunas and floras of the southern continents. For instance, the extinct saurian genus *Mesosternum*, which appears to have been allied to the Plesiosaurs of the Lias, is known from early Secondary strata in Brazil and South Africa, and nowhere else. Then, again, the remarkable Anomodont reptiles (*Dicynodon*, &c.) of South Africa are closely connected with those of India; while the respective alliances between the Labyrinthodont amphibians and the Mesozoic floras of South Africa, India, and Australia are too well known to need more than mention.

It appears, then, that, altogether apart from the new discovery, the common factors connecting the faunas and floras of the four great southern prolongations of the continental land of the globe undoubtedly point, not only to a more or less intimate connection between these several areas, but also to their more or less partial isolation from the more northern lands.

Reverting to the new discovery, it may be observed that our comparatively intimate acquaintance with the Tertiary faunas of Europe and North America renders it in the highest degree improbable that marsupials of an Australian type lived during that time in either of those areas. It is, however, quite possible that they may turn up at any time in Tertiary formations in Africa, while there is nothing to show that they may not also have existed in peninsular India. Indeed, if we put aside as improbable any connection by way of the Pacific between South America and Australia, it seems impossible to give any explanation of the occurrence of allied marsupials in Patagonia and Australia without the assumption that their ancestors existed in some part of the great area lying between eastern South America and Western Australia.

R. Lydekker.

PHOTOGRAPHY IN COLOURS.

The *Comptes rendus* for February 2, 1891, contained a brief note on colour photography, describing the method employed by M. G. Lippmann, who had been able to produce photographically the image of the spectrum with all its colours. A summary of this note was given in Nature at the time (see vol. xlviii., p. 360).

M. G. Lippmann, who has been continuing his researches, has communicated further results, which appear in the *Comptes rendus* for April 25 (No. 17, vol. cxiv.). These results show that we are not far off the solution of a question which has been the aim of all the latest photographic researches. The following is a translation of the note in question:—

In the first communication which I had the honour to make to the Academy on this subject, I stated that the sensitive films that I then employed failed in sensitiveness and isochromatism, and that these defects were the chief obstacle to the general application of the method that I had suggested. Since then I have succeeded in improving the sensitive film, and, although much still remains to be done, the new results are sufficiently encouraging to permit me to place them before the Academy.

On the albumen-bromide of silver films rendered orthochromatic by azalin and cyanin, I have obtained very brilliant photographs of spectra. All the colours appear at once, even the red, without the interposition of coloured screens, and after an exposure varying from five to thirty seconds.

On two of these *clichés* it has been remarked that the colours seen by transmission are very plainly complementary to those that are seen by reflection.

The theory shows that the complex colours that adorn natural objects ought to be photographed just the same as the simple colours of a spectrum. There was no necessity to verify the fact experimentally. The four *clichés* that I have the honour of submitting to the Academy represent faithfully some objects sufficiently diverse, a stained glass window of four colours, red, green, blue, yellow; a group of draperies; a plate of oranges, surmounted by a red poppy; a many-coloured parrot. These showed that the shape is represented simultaneously with the colours.

The draperies and the bird required from five to ten minutes' exposure to the electric light or the sun. The other objects were obtained after many hours of exposure to a diffuse light. The green of the foliage, the grey of the stone of a building, are perfectly produced on another *cliché*; the blue of the sky, on the contrary, was represented as indigo. It remains, then, to perfect the orthochromatism of the plate, and to increase considerably its sensibility.

NOTES.

THE Royal Society's *soirée* is being held as we go to press. We hope to give next week some account of the principal objects exhibited.

THE Bureau des Longitudes is sending an expedition to Senegambia to observe the total solar eclipse of April 1893.

THE first session of the Institution of Mining and Metallurgy is to be held in the theatre of the Geological Museum, Jermyn Street, on Wednesday, May 18, when the President, Mr. George Seymour, will deliver the inaugural address. There will be an inaugural supper at the Criterion.

AT the Royal Academy dinner Sir John Lubbock responded for science. He said that no class derived more benefit and enjoyment from works of art than men of science. Sir John referred also to the growing importance of art in relation to the material prosperity of the country. Our merchants and manufacturers, he said, could no longer rely entirely on excellence of material and solidity of workmanship, but had to look to artistic charm and beauty of design.

AT the annual meeting of the Royal Institution on May 2, the following gentlemen were elected officers for the ensuing year: the Duke of Northumberland, President; Sir James Crichton-Browne, Treasurer; Sir Frederick Bramwell, Secretary.

IT is reported from Melbourne that Sir Thomas Elder has decided not to send out another exploring expedition into Central Australia at present. He attributes the failure of his recent expedition, under Mr. Lindsay, to the severity of the season, the drought having been unusually trying.

ON May 7 the members of the Geologists' Association will make an excursion to Walthamstow, Mr. J. Walter Gregory acting as director. The object of the excursionists will be to examine sections on the Tottenham and Forest Gate Railway. The best section is about half a mile from St. James's Street, and shows the lower terraces of the Lea Valley gravels resting on a very eroded surface of London Clay. Masses of the London Clay stand up, which were probably once islets. The alterations in the position of the bed of the Lea are well shown by this cutting.

ON Tuesday next (May 10) Mr. Frederick E. Ives will begin a course of two lectures at the Royal Institution on photography in the colours of nature.

AT the meeting of the Franklin Institute, Philadelphia, on March 16, Mr. John Carbutt made some remarks on the results achieved by Mr. Frederick E. Ives in the field of colour photography, which, in his judgment, so far as practical results were concerned, were far in advance of anything that had as yet been accomplished elsewhere. Mr. Carbutt urged that it was eminently fitting for the Institute to recognize the value of the work of one of its own members, and moved that the subject of Mr. Ives's investigations and results in the field of colour photography should be referred to the committee on science and the arts for investigation and appropriate recognition. The motion was carried.

SIR JAMES CRICHTON-BROWNE delivered the annual oration at the 118th anniversary meeting of the Medical Society of London, held on Monday evening. He chose as his subject "Sex in Education." He showed that the female brain is lighter than that of the male, not only absolutely, but relatively to the respective statures and weights of the two sexes; that the specific gravity of parts of the female brain is less than that of corresponding parts of the male brain; and that the blood supply, which in the male is directed more towards the portions which are concerned in volition, cognition, and the ideo-motor processes, is in the female more directed towards portions which are mainly concerned in the discharge of sensory functions. Sir James urged the necessity of such structural differences being taken into account in the conduct of education; and, while disclaiming any intention of bringing a wholesale indictment against high schools for girls, he nevertheless held that some of their methods were capable of leading to great evils, especially when not controlled by a judicious and sympathetic mistress. He pointed out the difficulty of obtaining trustworthy information as to either the methods of many schools or their effects, more especially as the pupils themselves were often hostile to the inquiry; but he referred to one school at which he had been permitted to ascertain the facts, and in which he found that, out of 187 girls belonging to the upper and middle classes, well-fed and clad and cared for, and ranging from ten to seventeen years of age, as many as 137 complained of headaches, which in 65 instances occurred occasionally, in 48 frequently, and in 24 habitually. He cited the authority of Sir Richard Owen for the position that children have no business with headaches, and that something must be wrong in the school in which they frequently suffer from them. An account was given of the *modus operandi* of excessive brain work as a factor in the production of ill-health, and statistics were quoted to show the special liability of the female organism to disease at the period of life which the educator has seized on for his own. He attached great importance to loss of appetite, especially morning appetite, as a result of overstrain, and as one which was calculated to be itself the fruitful parent of other evils; and he strongly condemned the recent decision of the University of St. Andrews to open its classes in arts, science, and theology to women as well as to men, thus, as he declared, taking not a retrograde step, but a downhill step towards confusion and disaster. "What was decided amongst the prehistoric protozoa cannot be annulled by Act of Parliament; and the essential difference between male and female cannot be obliterated at a sweep of the pen by any Senatus Academicus."

THE weather during the past week has been unsettled generally, and showers of cold rain, hail, or sleet have occurred in many districts. The day temperatures have been low, with sharp frosts at night; on April 29 the thermometer on the grass fell as low as 20° in London, and heavy snow fell at Wick. From official reports for the week ended April 30 the temperature was several degrees below the mean for the week in all districts, although the bright sunshine had exceeded the normal amount. Gales were experienced on our exposed north and west coasts, but for the most part the wind has been light. Bright aurora has again been seen at several places. On May 1 the thermometer rose to 60° or more at several inland stations, but this improvement was not maintained. The winds, which during a few days were northerly and north-westerly, again became easterly over the whole of the British Isles, with unsettled and unseasonable weather.

A SPECIAL meeting of the New England Meteorological Society was held in Boston on April 6, when the recommendation of the Council to transfer the weather service of the Society to the National Weather Bureau at Washington, with the object of forming a New England Weather Service under the direction of that Bureau, was formally ratified. The New England Weather Service will continue to gather and publish observations of temperature and rainfall, and the monthly *Bulletin* will be continued as heretofore. While that part of the Society's work, in which the greater number of persons is involved, is thus transferred to the New England Weather Service, the meetings and investigations of the Society will be continued as during the past eight years. Three meetings will be held annually, and the proceedings will be published in the *American Meteorological Journal*, while the investigations will be published in the Annals of the Harvard College Observatory. In the *Bulletin* for March, it is stated that it is the intention of the Weather Bureau to make a special study of thunderstorms during the coming summer. The observations are to be made in several States, from May to August inclusive.

THE Deutsche Seewarte (Hamburg) has recently issued an atlas of thirty-five charts, with introductory text, showing the physical conditions of the Indian Ocean, on a similar plan to that published for the Atlantic Ocean some years ago. The rich materials at the disposal of the Seewarte have been discussed by Dr. Köppen and others in every form that can be of use both to seamen and physicists. Several charts are devoted to the currents, temperature and specific gravity, winds and monsoons, while the magnetic elements have been specially investigated by Dr. Neumayer.

THE Indian journals received by this week's mails report that Mr. John Eliot, the Meteorological Reporter to the Government of India, has returned to Simla from Chaman and Murree, where he has been establishing new meteorological observatories.

ON Friday last Colonel J. F. Maurice, Professor of Military Art and History to the Staff College, read at the meeting of the Royal United Service Institution a most interesting paper on military geography. This he described as a science dealing with all those conditions of the surface of the world which affected armies, campaigns, and battles. He sought to show how in the case of each of the great European countries strategic methods are affected by geographical conditions.

OPINIONS are being expressed by scientific workers in India in favour of the making of systematic experiments with snake poison. The Committee for the Management of the Calcutta Zoological Gardens are constructing, from private subscriptions a snake-house with the most modern improvements, which will contain specimens of all the principal poisonous snakes in the country. If the necessary funds were available, arrangements could be made to fit up a small laboratory in connection with the snake-house, for the purpose of conducting inquiries of all descriptions bearing upon the pathology of snake-bite and cognate subjects, and in future there would be no difficulty in arranging for the carrying out of any special experiments that might be required. It is understood that Dr. D. D. Cunningham, F.R.S., President of the Committee, would in that case be willing to take an active part in organizing and promoting such inquiries and carrying out such experiments, including the testing of the various alleged remedies for snake-bite which are from time to time brought to notice. A Calcutta paper, quoted by the *Pioneer Mail*, understands that if the Government of India will make a grant of Rs. 5000 towards this object, the Lieutenant-Governor will endeavour to meet the balance from Provincial funds.

THE well-known mycologist, Dr. Stephan Schulzer von Müggenburg, has just died at the age of ninety.

AT the coming "World's Columbian Exposition" at Chicago, it is proposed to have an exhibition of the "worst weeds" from all the States and Territories of the Union.

UNDER the editorship of Mr. E. M. Holmes a Catalogue has just been issued of the "Hanbury Herbarium" in the Museum of the Pharmaceutical Society. The collection consists of above 600 dried specimens of plants yielding products used in pharmacy, or believed to have medicinal properties, each specimen being labelled with its locality or the source whence it was obtained, and often accompanied by notes or extracts from letters of foreign correspondents. The collection was formed by the late Daniel Hanbury, F.R.S.; and, by the desire of his executors, who presented it to the Pharmaceutical Society, it is preserved in a separate room, known as the "Hanbury Room," on the premises of the Society in Bloomsbury Square.

THE second part of "Botanicon Sinicum," by Dr. Bretschneider, the learned physician to the Russian Legation in Pekin, has just been issued in Shanghai in the Journal of the North China Branch of the Royal Asiatic Society. The work deals with the botany of the Chinese classics, the object being to identify as far as possible the plants mentioned in the writings of Confucius, Mencius, and the other great sages of ancient China. Dr. Bretschneider takes each name in succession, supplies all the information given by native commentators on these ancient writers, and by lexicographers; then he gives all that can be gleaned from Japanese authorities, and follows this by the identifications of European students; concluding with the results of his own study and observation. Those whom Dr. Bretschneider's labours for the past twenty-five years have taught to expect profound learning, research, and thoroughness from him will not be disappointed in this work.

AMONG the contents of the new number of the Journal of the Royal Horticultural Society are the interesting papers read at the Conference on asters and perennial sunflowers, held at Chiswick in October last. The proceedings of the Conference were opened by an address by Mr. J. G. Baker, which is now printed. In this excellent address, in which the general botanical outlines of the subject are sketched out, Mr. Baker mentions that aster as it stands at present contains 200 or 300 species, and is concentrated in the United States. Nearly all our garden Michaelmas daisies belong to the species that grow wild in the Eastern United States. There are forty species of aster in the Rocky Mountains and fifteen in California, most of which are different from the eastern species, and have not been brought into cultivation. The papers published with Mr. Baker's address are on the genus aster, by Prof. G. L. Goodale; the Michaelmas daisy as a garden plant, by the Rev. C. W. Dod; perennial sunflowers, by Mr. D. Dewar; and the culture of sunflowers, by Mr. E. H. Jenkins.

THE "University Extension" movement has spread to the United States. We learn from the *Botanical Gazette* that Prof. J. M. Coulter, President of the University of Missouri, is lecturing to large University Extension classes in Evansville and New Albany, Indiana, and Louisville, Kentucky. Each course includes twelve lectures on the general morphology and physiology of plants.

AUSTRALIANS have had bitter experience of the mischief which rabbits are capable of doing, and now they seem likely to have trouble of a similar kind from the introduction of foxes. An Australian journal, quoted in the May number of the *Zoologist* says that foxes have already spread over a wide area, and are most destructive both to lambs and poultry. They attain greater size and strength in Australia than in England, and the mild climate is highly favourable to the increase of their numbers. "It must be very disheartening," says the writer, "to all who have stock of any kind to lose, to find themselve confronted by some new enemy introduced by thoughtless or selfish persons. If some energetic steps are not soon taken, nothing can prevent the spread of foxes over the whole continent."

MR. D. L. THORPE writes from Carlisle to the *Zoologist* that starlings in that district often reproduce the notes of the oystercatcher and curlew with wonderful accuracy. On April 3 he was surprised to hear the call of the landrail; it appeared to be the familiar "crake-crake" of that bird undoubtedly, but on further investigation he ascertained that a starling was reproducing the call-note of the rail. The bird had remembered his lesson of last summer remarkably well. Mr. Thorpe also mentions that, during severe weather in January last, a friend of his (the Rev. H. A. Macpherson) was astonished one day to hear the call-note of the common sandpiper repeated with such nicety as to completely deceive him, until the starling was detected in the act of rehearsing this summer cry.

A CAPITAL lecture on Egyptian agriculture was delivered by Prof. Robert Wallace at the meeting of the Society of Arts on April 27, and is printed in the current number of the Society's Journal. Referring to the Tewfikieh College of Agriculture, Prof. Wallace says that it was named in honour of the late Khedive (Tewfik Pasha), who took a special interest in its success. It had its origin in a desire which sprang up little more than two years ago in the Egyptian Government to develop the agricultural resources of the country by calling in the aid of science. The result has been a success far beyond the most sanguine anticipations. During the first year of its existence the College contained about 60 students, selected from about 300 applicants, and the numbers of the second, the current year, which began last October, have not fallen off. A number of the sons of large land-owners have taken advantage of the instruction offered, and it is hoped by this means to spread in all directions a knowledge of improved varieties of crop plants, improved rotations, improved implements, and improved methods, not neccessarily altogether new to the country, but deserving of being more widely known.

MR. W. F. LIESCHING, writing in the new number of the Selborne Society's Magazine on ants in Ceylon, says he saw one day a string of ants streaming forth, evidently in search of "pastures new." He flicked away the leader, and waited to see the result. An immediate halt was made by the foremost ants, and a scene of the utmost confusion ensued. The ants from behind kept arriving at the scene of the catastrophe, and there was soon a black crowd of ants huddling and jostling one another. Some detached themselves from the main group and took a turn round, trying to find traces of their leader. At last the tail end of the line arrived, and after brief consultation they all started off again, and a line soon began to unravel itself from the tangled mass moving back to the hole from which the whole company had so lately started on "pleasure bound or labour all intent." While Mr. Liesching was watching the return journey, a leech stung his leg. He took the creature off, and put it down in the line of march. Ants will carry off a worm, why not a leech? It was, however, most amusing to see how carefully all avoided the leech.

HENRY BRUGSCH PASHA read an interesting paper on Lake Mœris at the meeting of the Société de Géographie Khediviale on April 8. He had just returned from a visit to the neighbourhood of the supposed site of the lake, so that the subject was fresh in his mind. The *Times* has given a good abstract of the paper. M. Brugsch said there was abundant monumental evidence that at a very early period of Egyptian history there existed near the plateau of Hawara an immense basin of water, which gave its name to a whole province, the Fayûm, or "lake district." In ancient times there were forty-two divisions or nomes of Egypt, each having its own capital, local government, and *cultus*, and all more or less worshipping Osiris. From these the Fayûm was excluded. It was divided like the parent country into nomes with their governors, and save in the necropolis at Hawara was given over to the worship of Sebak, the crocodile god. It was known in the hieroglyphs as To She, the lake district, which in Coptic became P-ium, the maritime district, and survives to-day in the Arabic Fayûm. It is evident from the celebrated Fayûm papyrus, of which there are two copies, that the term Mer-uer, the great water or lake, was also applied to it; and perhaps herein lies the origin of the name "Mœris." The waters of this lake must have reached to the plateau of Hawara, the necropolis of the inhabitants of a town called Shed, on the site of which stands the modern city of Medinet-el-Fayûm. It was in ancient times a Royal residence, and contained a magnificent temple dedicated to Sebak, whose dimensions far exceeded those of the temples at Thebes. Tradition gives Amen-em-hat III. of the twelfth dynasty as the constructor of Lake Mœris, and his burial-place is the crude brick pyramid at Hawara; but fragments bearing the cartouches of Amen-em-hat I. and Usertsen II., found near Medinet, would prove it of more ancient date. Moreover, it was hardly possible that a town of such dimensions as Shed would be built at any distance from water. A canal named Hune, or Hunet, cut from the Nile, fed the lake and provided for the needs of the city; the mouth of it was called in the hieroglyphs La Hune, "the opening of the canal," a name which survives in the modern "El-Lahûn." There is an intetesting allusion to this "opening of the canal" in the celebrated Stela of Piankhi, written about the eighth century B.C. M. Brugsch also suggested that Ra-pa-ro-hunet, "the temple of the mouth of the canal," might give us the derivation of the word labyrinth.

WE have received the third number of *Natural Science*, the new monthly review of scientific progress. Among the contributors are Prof. G. Henslow, Mr. G. A. Boulenger, Sir J. W. Dawson, and Prof. W. C. Williamson.

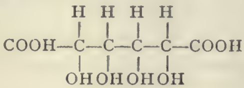
MESSRS. CHARLES GRIFFIN AND CO. have published the "Year-book of the Scientific and Learned Societies of Great Britain and Ireland." This is the ninth yearly issue. It presents lists of papers read before various Societies during the year 1891, together with information as to official changes. In most cases the Societies themselves have contributed the lists of papers. The names of those Societies concerning which no information has been received are entered in the index only.

Messrs. W. and A. K. Johnston have issued, under the authority of the Royal Agricultural Society of England, a valuable series of eight diagrams representing the life-history of the wheat plant. The diagrams are reproductions of original drawings by Francis Bauer, now in the Botanical Department of the British Museum, and are printed in colours. With each set is sent a pamphlet by William Carruthers, F.R.S., consulting botanist to the Society, entitled "The Wheat Plant: How it Feeds and Grows." This pamphlet consists of notes explanatory of the diagrams.

Dr. L. Meschinelli and Dr. S. Squinabol announce for publication a Tertiary Flora of Italy.

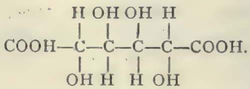
Four lectures upon recent stellar spectroscopy and the new star in Auriga will be delivered in Gresham College, by the Rev. Edmund Ledger, at 6 p.m. on the evenings of May 10, 11, 12, and 13.

Another contribution to our knowledge of the sugars and their related compounds is published by Prof. Emil Fischer in the current number of the *Berichte*. It relates to the constitution of the group of substances at the head of which stands dulcitol, $CH_2OH—(CHOH)_4—CH_2OH$, the hexahydric alcohol obtained from Madagascar manna, and prepared artificially by the reduction of milk sugar. It has already been established that the aldehyde corresponding to dulcitol is galactose, $CH_2OH—(CHOH)_4—COH$, the glucose obtained from many gums, and which is formed when milk sugar is boiled with dilute acids. Moreover, it has long been known that, when either dulcitol or galactose are oxidized by means of nitric acid, a dibasic acid of the composition $COOH—(CHOH)_4—(COOH)$ is produced. This acid, although expressed by the same formula as saccharic acid, the acid obtained by the oxidation of common cane-sugar, differs considerably in properties from that acid, and has been termed mucic acid. It is now known to be a geometrical isomer of saccharic acid—that is to say, the two compounds only differ with regard to the relative positions of the atoms comprising their molecules. Saccharic acid, as obtained from cane-sugar, is probably unsymmetrically built up, for its solution rotates the plane of polarization of light to the left. The main result of the work now described has been to show that the molecules of mucic acid are, on the contrary, symmetrically constructed, and that its observed optical inactivity is due to this fact. Theoretical considerations, based upon the postulates of the Van 't Hoff-Wislicenus hypothesis concerning the arrangement of carbon, hydrogen, and oxygen atoms in space, lead to the view that, of the ten possible geometrically-isomeric dibasic acids of the constitution $(CHOH)_4 . (COOH)_2$, two must be optically inactive. These two optically inactive isomers would be represented respectively by the formulæ



$$\mathrm{COOH{-}\underset{OH}{\overset{H}{C}}{-}\underset{OH}{\overset{H}{C}}{-}\underset{OH}{\overset{H}{C}}{-}\underset{OH}{\overset{H}{C}}{-}COOH}$$

and



$$\mathrm{COOH{-}\underset{OH}{\overset{H}{C}}{-}\underset{H}{\overset{OH}{C}}{-}\underset{H}{\overset{OH}{C}}{-}\underset{OH}{\overset{H}{C}}{-}COOH.}$$

One of these two was presumably mucic acid. It was evident that if the molecules possessed a configuration similar to that roughly indicated in one plane by either of the above formulæ, upon reduction to a monobasic acid there would be an equal number of chances of each of the two end carboxyl groups being attacked by the reducing agent and converted to CH_2OH groups. Consequently it was to be expected that equal quantities of two geometrically isomeric monobasic acids would be obtained, one dextro- and the other lævo-rotatory. Such has, indeed, been found by Prof. Fischer to be the case; for, upon reducing either the ethyl ester or the lactone of mucic acid (the acid itself being unattacked) by means of sodium amalgam, an optically inactive acid of the constitution $CH_2OH—(CHOH)_4—COOH$ was obtained, which formed a salt with strychnine yielding two distinct kinds of crystals, resembling the well-known complementary racemates of Pasteur. From these two kinds of crystals solutions of the free acids were obtained, which were respectively dextro- and lævo-rotatory, and each was again converted into mucic acid upon oxidation. One of these, the right-handed variety, was identical with the common galactonic acid prepared by oxidation of galactose. Moreover, by further reduction of the inactive acid, an inactive glucose was obtained, from which eventually common dextro- and also lævo-galactose were isolated by fermentation; and finally, by still further reduction of the galactose, dulcitol itself was obtained. Hence, the symmetrical structure of the dulcitol group may be considered as proved, and the work also completes the artificial synthesis of these compounds; for, given the synthesis of any one by the method previously described by Prof. Fischer, any of the others may be prepared from it by the processes now described.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss Beatrice Raymond; a Wild Swine (*Sus scrofa* ♀) from Tangiers, presented by Mr. E. H. Banfather; a Great Kangaroo (*Macropus giganteus*) from Australia, presented by Mrs. Frazer; a Purple Heron (*Ardea purpurea*), European, presented by Captain Woodward; a Bateleur Eagle (*Helotarsus ecaudatus*), a Tawny Eagle (*Aquila nævioides*) from Africa, presented by Captain Webster; a Raven (*Corvus corax*), European, presented by Mr. F. J. Stokes; seven Common Vipers (*Vipera berus*), British, presented by Mr. T. A. Cotton, F.Z.S.; a Rufous-necked Weaver Bird (*Hyphantornis textor*) from West Africa, purchased; an English Wild Bull (*Bos taurus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Sun-spots.—In the March number of the *Memorie della Società degli Spettroscopisti Italiani*, there are some interesting notes relating to spots and prominences. Prof. Tacchini gives a tabulated statement of the solar observations made at the Royal Observatory for the last three months of the year 1891. The most frequent records of faculæ occurred in the zones ±10° ±30°, only one being seen as high as the zone +40° +50°. As regards the spots, the greatest frequency of groups took place in the zones ±10° ±20°, 23 and 10 being observed in the north and south respectively.

Profs. A. Mascari and J. Fenyi both contribute some notes on the large group of spots visible in February last, the latter pointing out that the relation of the eruption to the large group was such that its centre was situated very near the side of the great nucleus of the south spot, but was entirely outside the spot itself.

M. H. Deslandres records also his observations with respect to the remarkable protuberance visible on March 3 at about 10 a.m. From spectroscopic observations he obtained a radial velocity of 200 kilometres per second, using the hydrogen and helium lines. He also obtained a photograph of the invisible ultra-violet region, which furnished him with "an exact image" of this protuberance. The H and K lines were extraordinarily brilliant, and the negative contained the entire series of ultra-violet rays of hydrogen. It may be mentioned that at the appearance of this large protuberance no special indication was registered on the curves of the magnetic instruments which M. Deslandres obtained from M. Wolf.

Prof. Tacchini communicated to the Paris Academy on April 25 the results of solar observations made at the Roman College during the first three months of this year. Spots and faculæ were observed on 56 days, viz. 19 in January, 19 in February, and 18 in March. The results are shown below:—

1892.	Relative frequency of spots.	Relative frequency of days without spots.	Relative magnitude of spots.	Relative magnitude of faculæ.
January	19·63	0·00	79·79	56·58
February	23·31	0·00	153·61	60·28
March	13·12	0·00	61·67	86·39

The following are the results for prominences:—

1892.	Days of observation.	Mean number.	Mean height.	Mean extension.
			″	°
January	13	6·39	39·6	1·6
February	13	7·00	36·0	1·6
March	14	8·14	36·4	2·3

The frequency and magnitude of spots during these months are much greater than during the preceding quarter, but prominences do not show a marked increase. No augmentation of this class of phenomena appears to have accompanied the great spot of February, if the mean numbers for the month be taken.

ECLIPSE OF THE MOON, MAY 11.—A partial eclipse of the moon will occur on May 11, and, if weather permits, it should be widely observed. The magnitude of the eclipse is 0·953, the moon's diameter being represented by 1. But although it is not total, important naked-eye observations can be made on the darkness of the shadowed moon for comparison with previous eclipses, and possessors of telescopes will doubtless take advantage of the occasion to obtain some new facts. The following times are from the "Nautical Almanac":—

		G.M.T. h.	m.
First contact with the penumbra,	May 11	7	55·9
,, ,, ,, shadow	,,	9	10·2
Middle of the eclipse	,,	10	53·4
Last contact with the shadow	,,	12	36·6
,, ,, ,, penumbra	,,	13	50·9

The first contact with the shadow occurs at 82° from the most northern point of the moon's limb, counting towards the east; the last contact at 41° from the same point, counting towards the west.

SPECTRUM OF SWIFT'S COMET (*a* 1892).—Mr. W. W. Campbell observed the spectrum of Swift's comet on April 6, by means of a spectroscope having one prism of 60° attached to the 36-inch of the Lick Observatory (*Astronomical Journal*, No. 262). The spectrum could be distinguished from about C to G. Three bright bands had the wave-lengths of their less refrangible edges determined as 5630, 5170·4, and 4723, by comparison with spark-spectra of iron and magnesium. The intensities of the bands were estimated to be in the ratio 1 : 6 : 2.

COMET SWIFT, 1892.—*Astronomische Nachrichten*, No. 3087, contains the following ephemeris of Swift's comet:—

For 12h. Berlin Mean Time.

1892.	R.A. h.	m.	s.	Decl. °	′	log *r*.	log Δ.	B.
May 5	22	45	25	+23	41·7			
,, 6	22	48	19	24	21·5			
,, 7	22	51	12	25	0·5	0·0608	0·1115	0·70
,, 8	22	54	3	25	38·7			
,, 9	22	56	53	26	16·2			
,, 10	22	59	41	26	52·9			
,, 11	23	2	28	27	28·9	0·0723	0·1236	0·62

The brightness on March 10 is taken as unity.

On the 5th the comet will be found to form very nearly an equilateral triangle with the stars λ and μ in Pegasus, while on the 11th it will be near β in the same constellation.

COMET SWIFT, 1892.—The spectrum of this comet has been observed by Prof. Konkoly, who contributes his observations to the *Astronomische Nachrichten*, No. 3087. The spectrum on April 1 appeared very bright, and showed five bright lines whose intensities were as follows:—I. = 0·4; II. = 0·3; III. = 1·0; IV. = 0·2; V. = 0·1, the continuous spectrum extending from λ = 580 to λ = 440.

The following measures are the means of five direct scale readings of the above-mentioned lines:—

I. = 558·82 μμ
II. = 544·94
III. = 516·30
IV. = 472·54
V. = 468·78

Similar observations were also repeated the next night, only by means of a larger telescope and spectroscope. The continuous spectrum was found to extend from λ = 559 μμ to λ = 449 μμ. The intensities were I. = 0·5; II. = 0·3; III. = 1·0; IV. = 0·2; V. = 0·1.

The mean values of the five measures obtained for each line were:—

I. = 558·40 μμ
II. = 543·82
III. = 516·26
IV. = 472·70
V. = 468·10

NOVA AURIGÆ.—*Astronomische Nachrichten*, No. 3083, contains some measurements and remarks by Prof. Konkoly relative to the spectrum of this Nova. Five lines were, according to him, very satisfactorily measured on March 20, and the means of six measures for each were as follows:—

I. = 531·80 μμ
II. = 516·50
III. = 501·95
IV. = 492·30
V. = 486·15

Using a 10-inch objective prism on the 21st, he found that II. was the brightest line, III. being somewhat feebler; I. was very weak, while IV. was not bright, but broad; V., again, seemed quite visible. With regard to the dark lines, he was only able to suspect them in the region of C and F (especially the latter), owing to their feebleness. The hydrogen lines on the 21st appeared feebler than those in γ Cassiopeiæ.

A NEW VARIABLE.—A circular (No. 32) that we have received from the Wolsingham Observatory contains the following:—

The star D.M. + 55° 1870—

16h. 39m. 49s.; + 55° 12′; 9·2

was found 7·3; 7·7, April 26; 29. Variable. Spectrum like Mira.

T. E. ESPIN.

THE TEMPERATURE OF THE BRAIN.

THE Croonian Lecture was delivered this year by Prof. Angelo Mosso, Professor of Physiology in the University of Turin. His subject was the temperature of the brain, especially in relation to psychical activity. Prof. Mosso's earlier investigations on the human brain only related to the blood circulation.[1] He then found that the blood pressure rises during psychical work, and that during such more blood is sent from the peripheral parts of the body. Prof. Mosso also found that the blood circulation in the brain showed fluctuations which are not dependent on psychical activity. These and other variations in the brain circulation led him to suspect that Dr. Schiff's theory about brain temperature as introduced into physiology required revision. In a published work on fatigue,[2] Prof. Mosso gave his views on the influence of psychical work on the organism, especially on the muscular force. We do not yet know what form of phenomena subserves the first condition of thought. Fatigue caused by psychical activity acts as a poison, which affects all organs, but especially the muscular system. This is clearly demonstrated by Prof. Mosso's investigations on men who have been subjected to great mental strain. The blood of dogs, fatigued by long racing, acts as a poison, and when injected into other dogs they exhibit all the symptoms of fatigue. The characteristic phenomena of fatigue depend more on nerve-cell products than on a deficiency of suitable material.

During investigation into the physical conditions during psychical activity, Prof. Mosso's attention was directed to the subject of the temperature of the brain. To avoid errors arising from blood changes he endeavoured to keep the blood temperature and that of the organs in agreement with that of the brain. For such a purpose he found that the thermo-electric pile which Dr. Schiff employed would not suffice, and he had therefore made by Baudin, of Paris, some very sensitive mercurial thermometers. The investigations made with the help of these instruments on the brain and blood temperatures bring to light new evidences of activity in the nerve centres. There are sometimes very extensive temperature developments under the influence of special excitements quite independent of psychical activity. The change in the nutrition of the nerve-cells, and not their specific activity, seems to be the most important source of heat in the brain. Thus Prof. Mosso would explain the marked effect on brain temperature of ordinary irritants where the increase is far higher upon the introduction of such than upon any psychical work done by the brain.

---

[1] "Kreislauf des Blutes in menschlichen gehirne," Leipzig, 1881.
[2] "Die Ermudung," Leipzig, 1892.

The following is an abstract of Prof. Mosso's Croonian Lecture:—

In his investigations on the temperature of the brain the author has employed, in preference to the thermo-electric pile, exceedingly sensitive mercurial thermometers, constructed specially for the purpose. Since each thermometer contains only four grams of mercury, the instruments respond very rapidly to changes of temperature, and a change of not more than 0°·002 C. can easily be measured by means of them. The author has studied the temperature of the brain, comparing it with that of arterial blood, of the muscles, and of the interior of the body. His observations were made on animals under the influence of morphia or various anæsthetics, and also on man.

The curves of the observations made show that in profound sleep a noise, or other sensory stimulus, is sufficient to produce a slight development of heat in the brain, without the animal necessarily awakening.

In profound sleep the temperature of the brain may fall below that of the blood in the arteries. This is due to the very great radiation of heat which takes place from the surface of the head.

The brain when subjected to the action of the ordinary interrupted current rises in temperature. The rise is observed earlier in the brain than in the blood, and the increase is greater in the brain than in the general blood-current or in the rectum. During an epileptic seizure, brought on by electrical stimulation of the cerebral cortex, the author observed within twelve minutes a rise of 1° C. in the temperature of the brain.

As a rule the temperature of the brain is lower than that of the interior of the body; but intense psychical processes, or the action of exciting chemical substances, may cause so much heat to be set free in the brain that its temperature may remain for some time 0°·2 or 0°·3 C. above that of the interior of the body.

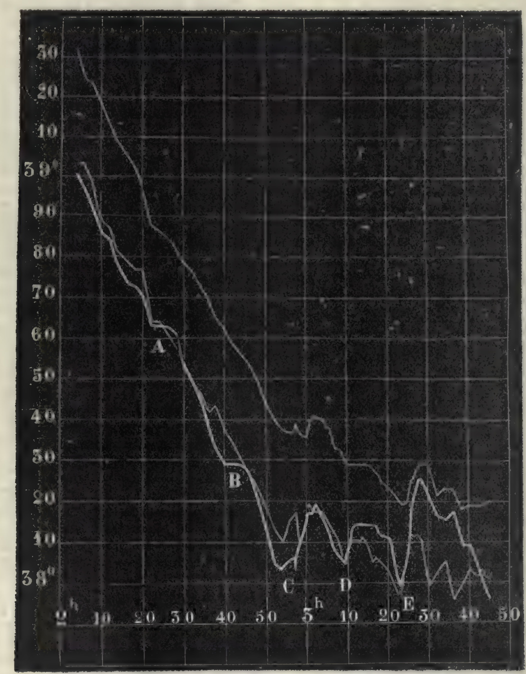


Fig. 1.—Dog rendered insensible with laudanum. The upper (thin) line represents the temperature of the interior of the body, the middle (thin line the temperature of the blood in the carotid artery, the third (thick) line the temperature of the brain. A, injection of 3 c.c. laudanum; B, blast of a trumpet; C, D, E, electric stimulation of the brain. The ordinate is marked in tenths of a degree Centigrade, the abscissa in periods of ten minutes.

When a dog is placed under the influence of curare, the temperature of the brain remains fairly high, while that of the muscles and that of the blood falls. The difference of temperature thus brought about is great and constant. In one instance, the temperature of the brain was 1°·6 C. above that of the arterial blood in the aorta. Such observations warn us not to regard the muscles as forming, *par excellence*, the thermogenic tissue of the body.

In order to show how active are the chemical processes in the brain, it is sufficient to keep the animal in a medium whose temperature is the same as that of the blood. When the effects of radiation through the skull are thus obviated, the temperature of the brain is always higher than that of the interior of the body, the difference amounting to 0°·5 or 0°·6 C.

Observations made while an animal is awake tend to show that the development of heat due to cerebral metabolism may be very considerable, even in the absence of all intense psychical activity. The mere maintenance of consciousness belonging to the wakeful state involves very considerable chemical action.

The variations of temperature, however, observed in the brain, as the result of attention, or of pain or other sensations, are exceedingly small. The greatest rise of temperature observed to follow, in the dog, upon great psychical activity was not more than 0°·01 C. When an animal is conscious, no change of consciousness, no psychical activity, however brought about experimentally, produces more than a slight effect on the temperature of the brain.

The author shows an experiment by which it is seen that, as part of the effect of opium, the brain is the first organ to fall in temperature, and that it may continue to fall for the space of eighteen minutes, while the blood and the vagina are still rising in temperature.

The author discusses the elective action of narcotics and anæsthetics. He shows that these drugs suspend the chemical functions of the nerve-cells. In a dog rendered completely insensible by an anæsthetic, one no longer obtains a rise of temperature upon stimulating the cerebral cortex with an electric current. These results cannot be explained as merely due to the changes in the circulation of the blood. The physical basis of psychical processes is probably of the nature of chemical action.

In another experiment, in an animal rendered insensible with chloral, the curves of temperature show that when the muscles of a limb are made to contract, the temperature of the muscles rises, but falls rapidly as soon as the stimulation ceases, soon returning to the normal. This is not the case, however, with the brain excited by an electric current. Here the stimulus gives rise to a more lasting production of heat; the temperature may continue to increase for several minutes after the cessation of the stimulation, indeed, often for half an hour. This may possibly explain why, upon an electric stimulation of the cerebral cortex, the epileptiform convulsions are not immediately developed, but only appear after the lapse of a latent period of several minutes.

This experiment may be made to show the elective action exercised upon the brain by stimulant remedies. The injection of 10 centigrams of cocaine hydrochlorate produces a rise of

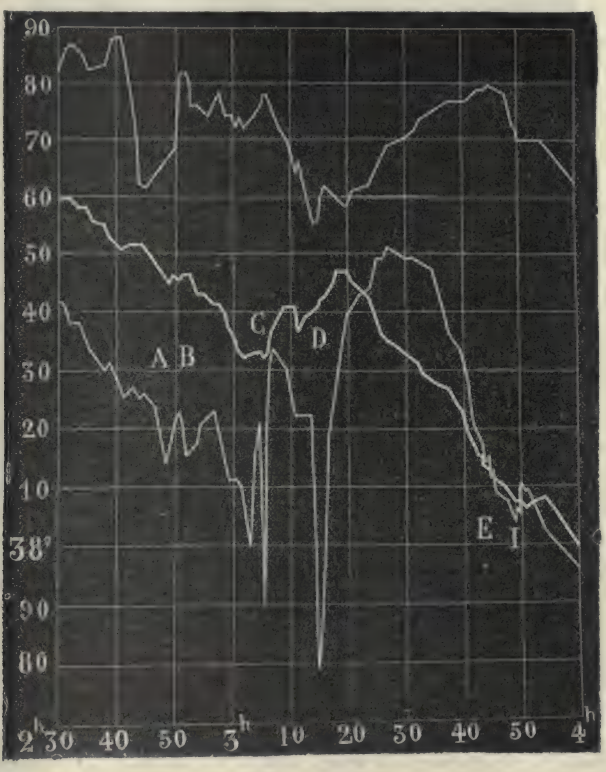

FIG. 2.—Dog (female) rendered insensible with chloroform and then with laudanum. The upper line represents the temperature of the vagina, the middle (thicker) line that of the brain, the lower that of the arterial blood in the carotid artery. A and B, psychical emotion; C, electric stimulation of the brain; D, injection of 14 c.c. laudanum (intravenous); E and I, electric stimulation of the brain.

temperature in the brain of 0°·36 C., without any change in the temperature of the muscles or of the rectum being observed. In a curarised dog, the intervention of the muscles being thereby excluded, the action of the cocaine may produce a rise of as much as 4° C. in the temperature of the brain, the author having observed a rise from 37° to 41° C. This shows that in arranging the calorific topography of the organism a high place must be assigned to the brain.

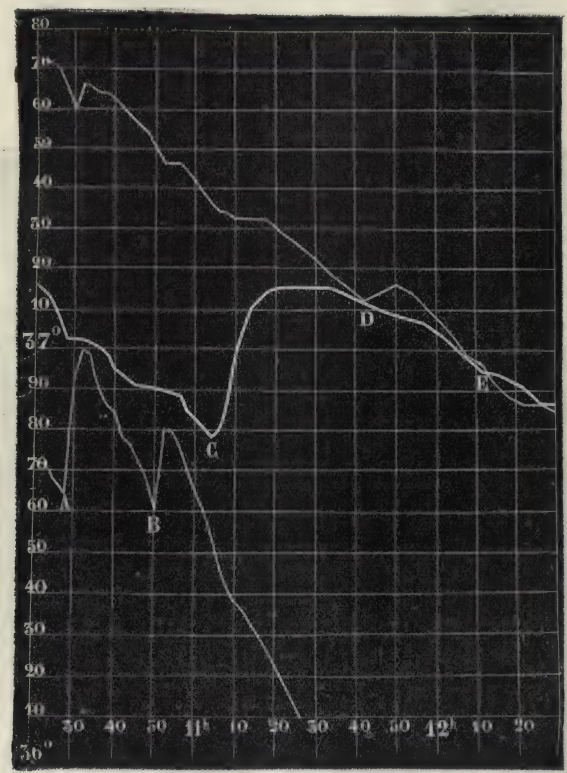

Fig. 3.—Dog rendered insensible with chloral. The upper line represents the temperature of the rectum, the middle (thicker) line that of the brain, the lower line that of the muscles of the thigh. A and B, electric stimulation of the muscles; C, injection of 10 centigrams of cocaine int the saphena vein; D, E, spontaneous variations in the temperature of the rectum.

THE MAGNETIC STORM OF FEBRUARY IN MAURITIUS.

At a meeting of the Meteorological Society of Mauritius, that took place on April 7, Mr. Meldrum read a short paper on the sun-spots, magnetic storm, cyclones, and rainfall of February 1892. The photographs of the sun that he exhibited, which were taken at the Royal Alfred Observatory from February 5 to 18, showed the very large group of spots, their approximate latitude on the 9th being from 6° to 16° south. Leading on to the occurrence of the great magnetic storm which began at 8h. 55m. on the 13th, he states that its commencement was distinctly recorded on the three curves, the horizontal force suffering the greatest disturbance. Up to 14h. the magnet was in oscillation, the force increasing, and reaching a maximum at 13h. 43m., after which it began to decrease, the minimum being reached at 0h. 15m. on the 14th. Further abrupt movements occurred at 4h. 30m. on the 14th, the oscillations, as shown by the curves, being very numerous, but at 19h. the magnets became more steady, and were quiet by 3h. on the 15th. The ranges obtained at the Mauritius Observatory were the largest ever recorded there.

Cyclones were not absent during this month. One lasted from the 11th to the 14th, and another from the 25th to the 28th, while a third was also experienced on the 21st and 22nd, about 550 miles south of Mauritius. The rainfall for February, as shown by returns from the numerous stations, was from 4·30 to 16·96 inches above the average for periods of 7 to 29 years. At Antoinette the fall for the month amounted to 12·53 inches, while that at Cluny came to 34·37 inches. St. Aubin and Nouvelle France came in for a considerable quantity of rain, the falls in the 24 hours ending at 8 a.m. on the 13th reaching the figures 5·00 and 18·20 inches respectively. Referring lastly to the magnificent displays of auroræ that have been observed both in Europe and America, he mentions that, although at Mauritius the sky was overcast, under similar conditions with respect to solar activity and terrestrial magnetism, a great display was visible in 1872. Mr. Meldrum, in his concluding remarks as to whether "there is a causal connection between solar activity (as indicated by outbursts on the sun) and magnetic disturbances, auroras, cyclones, and rainfall," remarks that with regard to the two former there can hardly be any doubt, but with regard to the two latter he is of opinion that a very close connection does exist, there being a considerable preponderance of evidence in its favour.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—*Annual Abstract of Accounts.*—The abstract of accounts of the University for the year ending December 31, 1891, has just been published. It exhibits both the accounts of the Curators of the Chest and the financial position of the University institutions. The receipts show an income of £66,986 12*s.* 9*d.*, against £65,175 17*s.* 2*d.* last year. The principal sources of internal income include estates £9978 12*s.* 8*d.*, the University Press £5000, University dues £11,153 5*s.*, examination fees £5659 1*s.*, degree fees £9600. The Proctorial fines amount to only £313, nearly £100 less than last year. In connection with the present agitation against Proctorial jurisdiction this item is interesting. The total payments amounted to £64,557 6*s.* 3*d.* There was transferred to capital account £2225 16*s.* 4*d.*, and a balance carried forward of £203 10*s.* 2*d.* In this item of expenditure, we find institutions and public buildings cost £19,085, the largest item under this head being the Bodleian Library £7772 4*s.* 4*d.*, while the Taylor Institution absorbed £2245. The expenses in connection with lectures in large towns amounted to £729 11*s.* 8*d.*, and the interest and sinking fund on loans for University purposes came to £6157 8*s.* 4*d.*

The loans account shows that the amounts remaining to be paid are £36,000 at 4 per cent. on the £60,000 New Schools Loan, and £7666 13*s.* 4*d.* at 2¾ per cent. on the £10,000 Physiological Laboratory Loan.

The University and the County Councils.—The report on the peripatetic teaching in scientific and technical subjects carried on in various country districts under the supervision of the Oxford Delegates for University Extension, acting in concert with the Technical Instruction Committees of County Councils during last winter, has just been published. The report states that the Oxford Delegates for University Extension were requested by the representatives of eight County Councils in England to provide for the delivery of 227 courses, embracing 2271 lectures, on chemistry, agriculture, geology, botany, veterinary science, physiology, and hygiene. These courses have been regularly attended by more than 10,000 persons in all grades of society.

The relations between the University Extension Committees of the different Universities and the County Councils, in reference to the matter of technical instruction, has now become so important, that a Conference was summoned last week, under the presidency of the Provost of Queen's College, to consider this connection, and to profit by the experience already gained, an experience, which in some cases extends over two years. It was felt that there are certain mistakes, inevitable in the commencement of any large scheme, which might be advantageously removed, so as to promote greater harmony, and possibly more economy in the fuller development of the scheme. Many organizing secretaries and others interested in the scheme attended the Conference, which extended over two days.

Two principal subjects were under discussion, first, the provision of summer courses of instruction in Oxford, Cambridge, and other University towns for teachers in elementary schools; secondly, the methods of organization of peripatetic teaching in regard to hours of lectures, classes, cost, and local management. In connection with the first point, it was announced that Oxford, Cambridge, and the Yorkshire College, Leeds, would be prepared to offer accommodation to students this summer; the Victoria University has, however, made no such provision. The method of procuring instruction in practical agriculture and experimental farming occupied much of the attention of the meeting, and much stress was laid upon the importance of securing the co-operation of farmers to look after the experimental stations.

On the matter of peripatetic teaching, it was felt by some that no very great assistance could be expected from the elementary teacher, and that reliance must be placed upon the teacher supplied by the Universities, in some cases advantageously supplemented by the teachers in secondary schools.

Not the least important feature in the Conference was the anxiety displayed by all present to urge on to the utmost of their power the great work of the dissemination of technical and scientific instruction, influenced solely by disinterested motives for the public service.

CAMBRIDGE.—Prof. Bonney, F.R.S., Fellow of St. John's College, will this year deliver the Rede Lecture in the Senate House, on Wednesday, June 15, at noon. The subject is "The Microscope's Contributions to the Earth's Physical History."

The Adams Memorial Committee have issued a circular inviting contributions towards the erection of a monument to the late Prof. J. C. Adams in Westminster Abbey. These may be paid to one of the treasurers (Dr. Searle, Master of Pembroke, and Prof. Liveing), or to one of the secretaries (Dr. Porter, Master of Peterhouse, Dr. Donald MacAlister, St. John's, and Dr. Glaisher, Trinity), or to the account of the Adams Memorial Fund at Messrs. Mortlock's Bank, Cambridge. We do not doubt that the invitation will meet with a generous response from the admirers of the great astronomer.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 28.—"On a Decisive Test-case disproving the Maxwell-Boltzmann Doctrine regarding Distribution of Kinetic Energy." By Lord Kelvin, Pres. R.S.

The doctrine referred to is that stated by Maxwell in his paper "On the Average Distribution of Energy in a System of Material Points" (Camb. Phil. Soc. Trans., May 6, 1878, republished in vol. ii. of Maxwell's "Scientific Papers") in the following words:—

"In the ultimate state of the system, the average kinetic energy of two given portions of the system must be in the ratio of the number of degrees of freedom of those portions."

Let the system consist of three bodies, A, B, C, all movable only in one straight line, KHL:

B being a simple vibrator controlled by a spring so stiff that when, at any time, it has very nearly the whole energy of the system, its extreme excursions on each side of its position of equilibrium are small:

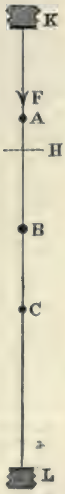
C and A, equal masses:

C, unacted on by force except when it strikes L, a fixed barrier, and when it strikes or is struck by B:

A, unacted on by force except when it strikes or is struck by B, and when it is at less than a certain distance, HK, from a fixed repellent barrier, K, repelling with a force, F varying, according to any law, or constant, when A is between K and H, but becoming infinitely great when (if at any time) A reaches K, and goes infinitesimally beyond it.

Suppose now A, B, C to be all moving to and fro. The collisions between B and the equal bodies A and C on its two sides must equalize, and keep equal, the average kinetic energy of A, immediately before and after these collisions, to the average kinetic energy of C. Hence, when the times of A being in the space between H and K are included in the average, the average of the *sum of the potential and kinetic energies of* A is equal to the average kinetic energy of C. But the potential energy of A at every point in the space HK is positive, because, according to our supposition, the velocity of A is diminished during every time of its motion from H towards K, and increased to the same value again during motion from K to H. Hence, the average kinetic energy of A is less than the average kinetic energy of C!

This is a test-case of a perfectly representative kind for the theory of temperature, and it effectually disposes of the assumption that the temperature of a solid or liquid is equal to its average kinetic energy per atom, which Maxwell pointed out as a consequence of the supposed theorem, and which, believed to be thus established, has been largely taught, and fallaciously used, as a fundamental proposition in thermodynamics.



It is, in truth, only for an approximately "perfect" gas—that is to say, an assemblage of molecules in which each molecule moves for comparatively long times in lines very approximately straight, and experiences changes of velocity and direction in comparatively short times of collision—and it is only for the kinetic energy of the translatory motions of the molecules of the "perfect gas," that the temperature is equal to the average kinetic energy per molecule, as first assumed by Waterston, and afterwards by Joule, and first proved by Maxwell.

"Researches on Turacin, an Animal Pigment containing Copper; Part II." By A. H. Church, M.A., F.R.S., Professor of Chemistry in the Royal Academy of Arts, London.

This paper is in continuation of one read before the Society in May 1869 (Phil. Trans., vol. clix. pp. 627–36). It contains an account of observations made by other investigators on turacin and on the occurrence of copper in animals; a table of the geographical distribution of the Touracos, and a list of the twenty-five known species; a chart of turacin spectra (for which the author is indebted to the kindness of Dr. MacMunn); and a further examination of the chemical characters and the composition of turacin. The more important positions established by the present inquiry are these:—

1. The constant occurrence in eighteen out of the twenty-five known species of *Musophagidæ*, of a definite organic pigment containing, as an essential constituent, about 7 per cent. of copper.

2. The "turacin-bearers" comprise all the known species of the three genera, *Turacus*, *Gallirex*, and *Musophaga*; while from all the species of the three remaining genera of the family *Musophagidæ*—namely, *Corythæola*, *Schizorhis*, and *Gymnoschizorhis*—turacin is absent. Furthermore, the zoological arrangement of the genera constituting this family is in accord with that founded on the presence of turacin.

3. The spectrum of turacin in alkaline solution shows, besides the two dark absorption bands previously figured, a faint broad band on either side of line F, and extending from λ 496 to λ 475.

4. The spectrum of *isolated* turacin in ammoniacal solution shows, besides the three bands already named, a narrow fourth band, lying on the less-refrangible side of line D, and extending from λ 605 to λ 589. It probably arises from the presence of traces of the green alteration-product of turacin formed during the preparation of that pigment in the isolated condition; an alteration-product which is likely to prove identical with Krukenberg's turacoverdin.

5. Turacin in ammoniacal solution remains unchanged after the lapse of twenty-three years.

6. Turacin in the dry state, when suddenly and strongly heated, yields a volatile copper-containing red derivative, which, though undissolved by weak ammonia-water, is not only soluble in, but may be crystallized from, ether.

7. Turacin in the dry state, when heated in a tube surrounded by the vapour of boiling mercury, becomes black, gives off no visible vapour, is rendered insoluble in alkaline liquids, and is so profoundly changed that it evolves no visible vapour when afterwards strongly heated.

8. The accurate analysis of turacin offers great difficulty. The percentage composition, as deduced from those determinations which seem most trustworthy, is—

Carbon	53·69
Hydrogen	4·60
Copper	7·01
Nitrogen	6·96
Oxygen	27·74

These numbers correspond closely with those demanded by the empirical formula $C_{82}H_{81}Cu_2N_9O_{32}$, although the author lays no stress upon this expression.

9. Turacin presents some analogies with hæmatin, and yields, by solution in oil of vitriol, a coloured derivative, turacoporphyrin. The spectra of this derivative, both in acid and alkaline solution, present striking resemblances to those of hæmatoporphyrin, the corresponding derivative of hæmatin. But copper is present in the derivative of turacin, while iron is absent from its supposed analogue, the derivative of hæmatin.

Chemical Society, April 7.—Dr. W. H. Perkin, F.R.S., Vice-President, in the chair.—The following papers were read:—The separation of arsenic, antimony, and tin, by J. Clark. The mixed sulphides of arsenic, antimony, and tin obtained in the ordinary course of quantitative analysis are dissolved in a strong solution of ferric chloride in hydrochloric acid, and the arsenic distilled off and weighed as trisulphide. The residual liquor contains the antimony as trichloride, and the tin as stannic chloride, together with ferrous and ferric chlorides. Without removing the iron salts, the antimony is precipitated with hydrogen sulphide in a tepid solution containing from one-quarter to one-third of its volume of hydrochloric acid and a considerable quantity of oxalic acid. The precipitate, which is free from tin, is washed first with water, then with alcohol, and finally with carbon disulphide, and weighed as Sb_2S_3 after being dried at 130°. When the antimony precipitate is large, it must, after drying, be digested in carbon disulphide to extract the whole of the sulphur. To obviate this, the author reduces the excess of ferric chloride with thin sheet-iron, as soon as the yellow colour has disappeared the undissolved iron is removed, and the antimony which has come down is redissolved by cautiously adding ferric chloride till the solution is distinctly yellow, showing that all the tin is in the stannic state; a warm solution of oxalic acid containing about one-third of its volume of hydrochloric acid is then added, and the precipitated antimony trisulphide washed and weighed as above. After removal of the antimony, the hydrogen sulphide is expelled by boiling, the oxalic acid decomposed with potassium permanganate, the tin precipitated in a hot solution with hydrogen sulphide, and allowed to stand till cold. The stannic sulphide thus obtained is filtered, washed, ignited, and weighed as SnO_2.—Platinous chloride and its use as a source of chlorine, by W. A. Shenstone and C. R. Beck. The authors have examined chlorine prepared from six specimens of platinous chloride of independent origin, and have found oxygen and hydrogen chloride to be present in them all. From these results they conclude that platinous chloride made by any of the processes hitherto recommended, including that lately suggested by L. Pigeon, contains a very perceptible quantity of some basic compound, which gives off water, together with the gases previously mentioned. It was also noticed that after mercury has been exposed to the action of chlorine, in the presence of a trace of water, it becomes capable of absorbing hydrogen chloride; it is not yet certain whether this action depends on the presence of oxygen or not.—Note on the adhesion of mercury to glass in the presence of halogens, by W. A. Shenstone. The author finds that carefully purified chlorine, bromine, and iodine affect mercury like ozone, causing it to adhere to glass in a remarkably perfect manner.—The decomposition of mannitol and dextrose by the *Bacillus ethaceticus*, by P. F. Frankland and J. S. Lumsden. The authors find that the products of fermentation of both mannitol and dextrose by *B. ethaceticus* consist of ethyl alcohol, acetic acid, carbon dioxide, hydrogen, and traces of succinic acid. A considerable quantity of formic acid is also formed when the fermentation proceeds in a closed space, whilst, in fermentations conducted in flasks merely plugged with cotton wool, formic acid, except in traces, is an exceptional product. This phenomenon has previously been found to occur with fermentations by means of *B. ethacetosuccinicus*. Formic acid is doubtless a primary product of the fermentation, but tends to break down into carbon dioxide and hydrogen. In the closed space, however, equilibrium is soon established between the formic acid and its decomposition products, and part of the formic acid is subsequently found in the solution. This view is supported by the fact that carbon dioxide and hydrogen are found in almost equal volumes. The proportions in which the several products are obtained from mannitol are approximately represented by the equation—

$$3C_6H_{14}O_6 + H_2O = C_2H_4O_2 + 5C_2H_6O + 5CH_2O_2 + CO_2.$$

In the case of dextrose the products occur in the proportions: $2{\cdot}5C_2H_6O : 1{\cdot}5C_2H_4O_2 : 3CH_2O_2 : CO_2$. There is a close qualitative and quantitative resemblance between fermentations by *B. ethaceticus* and those occurring by means of the *Pneumococcus* (Friedländer), which renders it probable that this ethacetic decomposition is a very general and typical form of fermentative change.—The preparation of glycollic acid, by H. G. Colman. Glycollic acid may be readily prepared by boiling concentrated potassium chloracetate solution for 24–30 hours. The liquid is then distilled under reduced pressure, and the residue mixed with acetone. On evaporation of the filtered solution, glycollic acid crystallizes out in colourless crystals, containing only about 0·5 per cent. of ash. This acid would seem to be dimorphous. Glycollic anilide may be prepared by heating glycollic acid for some time to 240°, and boiling the product with aniline.—Researches on silicon compounds and their derivatives; Part vi. The action of silicon tetrachloride on substituted phenylamines, by J. E. Reynolds. Diphenylamine combines with silicon tetrachloride to form an unstable addition compound, which is decomposed below the boiling-point of benzene. Ethylaniline is easily acted on by the tetrachloride, ethylaniline hydrochloride separates, and a compound having the composition $Si(PhNEt)_4$ is formed. Diethylaniline is but feebly acted on by silicon tetrachloride; the compound $PhNEt_2HCl$ is formed, and probably a substance of the composition $Si(C_6H_4NEt_2)_4$.—Chemistry of the compounds of thiourea and thiocarbimides with aldehyde-ammonia, by A. E. Dixon. The alkyl and allied thiocarbimides react with aldehyde-ammonia, in accordance with the following equation—

$$R.NCS + 2R'CH(OH)NH_2 = CSN_3H_2R(CHR')_2 + 2H_2O.$$

It was suggested that some connection might exist between the class of substances so formed and the compounds obtained by the action of thiourea on the aldehyde-ammonias. From the great similarity in behaviour of the compounds derived from the two sources, the author infers that they are members of the same class. Though thiourea and aldehyde-ammonia readily interact, it was found impossible, under any conditions, to cause substituted thioureas to act on aldehyde-ammonia. The author considers that this fact indicates that the monosubstituted thioureas are of the form  $HN:C\begin{cases}NH_2\\SH\end{cases}$ and not $CS\begin{cases}NHR.\\NH_2\end{cases}$. —The atomic weight of boron, by J. L. Hoskyns-Abrahall. The deceased author determined the atomic weight of boron by estimating the amount of silver necessary to precipitate the bromine from a known weight of boron bromide. The mean atomic weight obtained is 10·816 ± 0·0055. Silver is taken as 107·923, and bromine as 79·951.

Physical Society, April 8.—Dr. J. H. Gladstone, F.R.S., Past President, in the chair.—Mr. Walter Baily read a paper on the construction of a colour map. By the term "colour map," the author meant a diagram, each point of which defines by its position some particular colour. Captain Abney had shown that all colours, except the purples, could be formed by adding white light to some spectrum colour, whilst all except the greens could be made to produce white by the addition of some spectrum colour. There were, therefore, two ways in which colours, other than greens and purples, could be indicated. In one of these, the ordinate of a point might represent the spectrum colour by its wave-length, and the abscissa, measured to the right of a vertical spectrum line, the amount of white light to be added to the spectrum colour to produce the colour represented by the point. In the other, the abscissa of a point situated on the left of the spectrum line represents the quantity of white light produced by the addition of the spectrum colour to the colour indicated by the point. Regarding the spectrum colours as formed by mixing three primary colours (red, green, and violet) in varying proportions, three curves were drawn to the left of the spectrum line whose abscissæ represented respectively the proportions of the three primary colours present in the corresponding spectrum colour. Horizontal distances from any point to these curves show the proportions in which the primary colours are to be mixed produce to the particular colour defined by that point. For points between the curves, the horizontal distances are not measured all in one direction, and therefore indicate abnormal or imaginary colours. The principle of the map was further illustrated by a sort of colour staff, consisting of three horizontal lines representing the three primary colour sensations (see figure) of such luminosities that equal lengths of the three lines indicate white light. If points, R, G, V, be taken in these lines, then a cross line A will cut off lengths A R, A G, A V, whose mixture will produce a certain colour. If now A be moved parallel to itself towards the right, the colour will change by the addition of white light; moving A to the left means a subtraction of white light. When R, G, and V are properly chosen, a certain position, S, of the cross line, corresponds to a spectrum colour. The whole of the series of colours which can be obtained by adding white light to that spectrum colour can then be represented by sliding A towards the right. Positions S′ and A′ give colours complementary to S and A. The distinguishing features of such a series of colours are the differences R − G and G − V, and the author calls the ratio $\frac{R-G}{G-V}$ the "colour index." Passing up the spectrum from red to violet, the index, which is first large and positive, diminishes and becomes negative between yellow and blue; it then passes through infinity, and becomes positive and decreases to zero. The subject of determining the indexes of colours resulting from the mixture in various proportions of two other colours whose indexes were known, was considered, and diagrams showing the various curves, exhibited. Experimental methods of determining the proportions of the primary colour sensations constituting the spectrum tints were described. A visitor inquired how the author's system provided for the class of colours outside the red and violet. He also desired a definition of "white light." He himself had never been able to produce pure white by mixture of colours, for a reddish violet generally resulted. On the other hand, he found it possible to match any other colour by mixture. Prof. Carey Foster thought Helmholtz was the first to propound the law which the author had attributed to Captain Abney. He wished to know how the amounts of colour sensation were supposed to be measured. White light he considered ought to be defined as light in which a normal eye, not fatigued, could perceive no preponderance of any colour. Mr. Blakesley said that if white light was a mixture, and only two unknowns were necessary, then any colour could be produced by the mixture of two other colours. Dr. Sumpner pointed out that white light was by no means a constant colour, but depended greatly on the source. He thought the author's map of a more absolute nature than that proposed by Maxwell. Dr. Hoffert inquired whether the intensities of each spectrum colour had been considered equal or otherwise taken into account, and also whether the results arrived at would be true for intensities other than those chosen. Mr. Baily, in reply, said Captain Abney had found the light from the crater in the positive carbon of an electric arc to be the most constant white, and in his method of experimenting errors due to variations of the source cancelled. The quantity of any spectrum colour was defined by the breadth of the band used, the breadth being small and measured on the scale of wave-lengths.—A paper on a mnemonic table for changing from electro-static to practical and C.G.S. electro-magnetic units was read by Mr. W. Gleed. In the table, which is given below, the abbreviations *Stat* and *Mag* are used to denote the electro-static and electro-magnetic units respectively, and v stands for 3×10^{10}:—

	Units of				
	Capacity.	Resistance.	Potential.	Current.	Quantity.
Powers of 10 for practical and magnetic units	9	9	8	1	1
Small unit	Stat	Mag	Mag	Stat	Stat
Practical unit	Farad	Ohm	Volt	Ampere	Coulomb
Large unit	Mag	Stat	Stat	Mag	Mag
Factor for Stat and Mag	v^2	v^2	v	v	v

To form the table, the numbers 981 in the middle of the second line give the value of g. The end numbers are duplicated, giving 99,811. Below them in the fourth line come the names of the practical units, the initials forming the word *fovac*. Remembering that the electro-magnetic units of resistance and potential were too small for practical use, one places Mag above both Ohm and Volt. Ohm's law and definitions then show that the practical units of capacity, current, and quantity must be less than the electro-magnetic units, hence Mag must be written below Farad, Ampere, and Coulomb. Since the practical units are intermediate in magnitude between Stat and Mag, the vacant spaces are then filled in by Stat. The v's in the bottom line are added from memory. Several examples showing the use of the table are worked out in the paper accompanying the table.—A paper on the law of colour in relation to chemical constitution, by William Akroyd, was read by Mr. Blakesley. The author has observed that, in cases of compounds having a constant radical, R, and a variable radical R′, the effect of an increase in the molecular weight of R is to make the colour of the compound tend towards the red end of the colour scale. Exceptions are, however, noted. Mr. H. M. Elder questioned the author's conclusions, saying that in many cases the colours tend towards blue.

Anthropological Institute, April 26.—Dr. Edward B. Tylor, F.R.S., President, in the chair.—Prof. R. K. Douglas read a paper on the social and religious ideas of the Chinese, as illustrated in the ideographic characters of the language. The paper begins with a short introduction, showing that the Chinese ideographic characters are picture-writings, and that as such they supply an interpretation of the meaning of words as these were understood by the inventors of the characters representing them. Following on this is an account of the earliest or hieroglyphic form of the writing, with examples, and the development of this resulting in the ideographic characters. These are taken as being illustrative of the ideas of the people on political, social, scientific, and religious ideas. For example, the importance which was attached to the qualities of a sovereign is exemplified in the choice of the symbol employed to express a supreme ruler, the component parts of which together signify "ruler of himself." By means of the same graphic system a kingdom is shown as "men and arms within a frontier." Passing to the social habits of the people, their domestic life is illustrated by a number of ideograms descriptive of their household arrangements and relationships. In succession are traced in the written characters the ideas associated with men and women, their virtues and their failings; the notions associated with marriage; and the evidences of pastoral as well as of agricultural habits among the people. Turning to the popular religious faiths it is shown how prominent is the belief in the god of the soil, whose presence brings blessings, and whose averted countenance is followed by misfortune. The ideas associated with objects of nature are next treated of, and the paper concludes with references to the coinage of the country as described in the ideograms employed to represent its various forms.—Mr. Joseph Offord, Jun., read a paper on the mythology and psychology of the ancient Egyptians.

Entomological Society, April 27.—Mr. Robert McLachlan, F.R.S., Treasurer, in the chair.—Mr. C. G. Barrett exhibited, for Mr. Sabine, varieties of the following species: viz. one of *Papilio machaon*, bred by Mr. S. Baily, at Wicken, in 1886; one of *Argynnis lathonia*, taken at Dover in September 1883; one of *A. euphrosyne*, taken at Dover in 1890; and one of *A. selene*, taken at St. Osyth, in 1885, by Mr. W. H. Harwood. He also exhibited a long series of *Demas coryli*, reared by Major Still from larvæ fed exclusively on beech, which he said appeared to be the usual food of the species in Devonshire, instead of hazel or oak. Mr. Barrett also exhibited, for Mr. Sydney Webb, a number of varieties of *Arge galathea*, *Lasiommata megæra*, *Hipparchia tithonus*, and *Cœnonympha pamphilus*, from the neighbourhood of Dover.—The Rev. J. Seymour St. John exhibited a variety of the female of *Hybernia progemmaria*, taken at Clapton in March last, in which the partially developed wings were equally divided in point of colour, the base being extremely dark and the outer portion of the wing very pale.—The Rev. Canon Fowler made some remarks on the subject of protective resemblance. His attention had been recently called to the fact that certain species of *Kallima* apparently lose their protective habit in some localities, and sit with their wings open; and Dr. A. R. Wallace had informed him that he had heard of a species sitting upside down on stalks, and thus, in another way, abandoning its protective habits. Mr. W. L. Distant referred to certain species of South African butterflies, which, when at rest, were protected by their resemblance to the plants on which they reposed, or by their resemblance to the rocks on which they settled, but which frequently abandoned their protective habit and sat with open wings. Mr. Barrett Mr. McLaclan, Mr. Jacoby, Mr. Champion, Mr. H. Goss Canon Fowler, and Mr. Frohawk continued the discussion.—Mr. Goss informed the meeting that, in pursuance of a resolution of the Council passed in March last, he and Mr. Elwes had represented the Society at the recent Government inquiry as to the safety and suitability of the proposed rifle range in the New Forest, held at Lyndhurst by the Hon. T. W. H. Pelham, on the 20th, 21st, 22nd, and 23rd inst., and that they had given evidence at such inquiry.

PARIS.

Academy of Sciences, April 25.—M. d'Abbadie in the chair.—On the photography of colours (second note), by M. G. Lippmann. In his first communication on colour photography, M. Lippmann remarked that the results would have been much better if isochromatic films had been employed. He has now obtained some new pictures, and presented them to the Academy. Silver bromide films, stained with azalin and cyanin, were used in connection with the arrangement previously explained. The solar spectrum appears to have been photographed in all its beauty with an exposure of about thirty seconds. On two of the plates the colours viewed by transmitted light are seen to be complementary to those given by reflected light. A photograph of a window containing red, green, blue, and yellow glasses appears to be very satisfactory. Others of a group of drapery and a parrot were obtained with an exposure of from five to ten minutes. Several hours' exposure were given to a plate of oranges surmounted by a poppy, diffused light being employed. In all cases the forms of the objects were reproduced as well as the colours.—On the means employed in producing rain artificially, by M. Faye. The author states Espy's opinions on the formation of cyclones and other atmospheric disturbances, and quotes a letter on rain-making experiments carried out in Florida in 1857. He is of opinion that the theory which led to the experiments is wrong. For, according to M. Faye, (1) water-spouts, tornadoes, and cyclones move quickly during calm weather: ascending columns of heated air do not move. (2) Tornadoes and water-spouts whirl vigorously in a certain direction: ascending columns of air do not rotate, or only do so very faintly. (3) Tornadoes and water-spouts are cold in the centre: ascending columns of air are warm. (4) Tornadoes and water-spouts descend from clouds: ascending columns rise towards the clouds, &c.—On the division, according to terrestrial latitudes and longtitudes, of the geological groups on the earth, by M. Alexis de Tillo. The following are the sums of the distribution of groups of rocks, &c., given in the tables for every ten degrees of latitude; the dimensions are expressed in millions of square kilometres:—

Pre-Cambrian ...	19·85	Glaciers ...	1·94
Primary ...	17·18	Igneous rocks ...	3·96
Secondary ...	19·85	Coral islands ...	0·02
Tertiary ...	8·71	Region { Explored	98·03
Quaternary ...	19·17	Region { Unexplored	36·16
Gravels ...	7·35	Total ...	134·19

Tables are also given showing the proportion of the known surface of the globe occupied by each of the above groups, and also showing the distribution in longitude.—Observations of two new planets, discovered at Nice Observatory on March 22 and April 1, by M. Charlois. Observations for position are given.—Photography of the Ring Nebula in Lyra, by M. F. Denza.—Solar observations made during the first quarter of 1892, by M. Tacchini. (See Our Astronomical Column).—On a problem in mathematical analysis connected with equations in dynamics, by M. R. Liouville.—Direct and indirect measures of the angle which the surface of a liquid makes with glass which it does not wet, by M. C. Maltézos.—On thermo-electric phenomena produced by the contact of two electrolytes, by M. Henri Bagard.—Addition to the law of the position of nervous centres, by M. Alexis Julien.—Analysis of a chromiferous clay from Brazil, by M. A. Terreil.—On the waters and muds of the lakes of Aiguebelette, Paladru, Nantua, and Sylans, by MM. L. Duparc and A. Delebecque.

BRACHIOPODS OF THE ALPINE TRIAS.

Brachiopoden der Alpinen Trias. Von A. Bittner. *Abhandl. d. k. k. geologischen Reichsanstalt*, Bd. xiv. 4to, 325 pages, 41 plates, and numerous zincotypes in the text. (Vienna: A. Hölder, 1890.)

BOOKS on Triassic fossils, helping as they do to bridge over the gap in our knowledge of those life-forms that led from the ancient times to the middle ages of earth-history, will always be welcomed by both geologist and biologist, especially when, as in the fine work before us, they show signs of wide learning and elaborate research, and are accompanied by such figures and diagrams as place their stores of information within easy reach of all.

The Triassic rocks and Brachiopods best known to English collectors, and indeed to geologists in general, through the writings of Münster, v. Klipstein, and Laube on the one hand, and Suess and Zugmayer on the other, are those of the St. Cassian argillaceous beds and of the Hallstatt limestone. Besides these, the Brachiopods of the Alpine Muschelkalk have been largely worked out by Schauroth and Boeckh. In addition to those from these well-known horizons, Mr. Bittner surveys the Brachiopod faunas from a large number of other beds, including the Rhætic, few of which beds have been systematically worked before, but all of which may be compared with those of the above-mentioned better-known types.

Mr. Bittner has divided his work into two parts: the first, of 287 pages, being devoted to the description of species and the comparison of faunas; the second dealing with the morphology and distribution of the several genera. It will be convenient to follow a similar order in this article.

Part I. follows primarily a stratigraphical, and secondarily a topographical arrangement, so that the species are described under various faunas. In one place, however, the author stops to give us two interesting essays, one on his new genus *Halorella*, the other on the Triassic species of *Rhynchonella*, both of which should by rights have come in the second part of his work.

The descriptions are based chiefly on materials in the Museum of the Geologische Reichsanstalt and the Hofmuseum in Vienna, although a very large number of other collections—private and public—have been consulted by the author. Among these, however, we fail to notice the British Museum, which contains many of v. Klipstein's types. Mr. Bittner, it should be mentioned, invites collectors and others to send him all their material, and promises to determine the species carefully and to describe any new ones. The present volume is sufficient guarantee that the work will be carefully done.

It may well be imagined that the task set before our author was no light one. There appear to be 398 species of Brachiopods in the Trias of the Alps, and of these 216 are named for the first time in this work. But we wish that Mr. Bittner had made his book a little more of what one expects it to be from its size and scope—namely, a monograph of the Brachiopods of the Alpine Trias. Such a monograph would have included a diagnosis, if not a figure, of every species of Brachiopod known to occur in these beds; it would have summarized the literature of the subject, and it would have shown at a glance under each species in what beds and at what localities it occurred. Such a work, which need not have been a page longer than the present, would have been worth a library to students of these fossils. The author, however, has elected merely to crowd our shelves with one more book, and not even a book in the highest sense of the word. He has unfortunately not thought it necessary to give even descriptions of previously named species, unless he has something new to say about them, while his whole volume is innocent of any serious attempt at a diagnosis. Here is an example—no unfavourable one—of his method:—

> "*Rhynchonella Attilina*, nov. sp."
>
> "A small *Rhynchonella* occurring in numbers, which at first sight reminds one of the above-described *Rh. trinodosi m.* The simplest examples are very near that species and easily confused with it."

He then goes on to contrast *R. Attilina* with *R. trinodosi*, point by point, for twenty-seven lines, and so ends without any independent description of his new species, and with nothing to say how it differs from the ninety other Triassic species of the genus, not to mention the rest. And there are many worse instances than this.

We are aware that Mr. Bittner is by no means the only offender in this respect; were he so, our complaints would be unnecessary. He is merely an example of a body of writers, far too numerous in our own country, who seem to have the notion that this sort of thing is science. It is what science has to put up with, and if possible to make science out of; but there is generally about as much science in it as in an auctioneer's catalogue. The writers in question seem never to have heard of Linnæus. Had they studied his writings, they would understand that, for systematic purposes, the diagnosis is everything, that every new species described often necessitates a re-diagnosing of all other species in the genus, and in many cases involves a fresh diagnosis of the genus itself. Were this appreciated, fewer synonyms would disgrace our lists.

To return to Mr. Bittner, whose work is after all more scientific than that of most of these name-mongers. It is noticeable that he, as a rule, gives no measurements, leaving it to readers to gather these from the plates. The task of calculating average measurements is of course irksome; still it is often possible to compare species more accurately by their means than by any other.

Neither does our author ever take the trouble to inform us of the meanings of his trivial, or even generic names. "Why *R. trinodosi?*" we ask, and infer—though from nothing under the head of the species itself—that it is due to the association of the species with *Ceratites trinodosus.* But there are many names that still remain to the present writer unsolved enigmas: such are *S. pia*, *S. avarica* (unless this means *avaricensis*), and *R. generosa.* It is also rather difficult to understand why three species of Rhynchonella, all from the same district, should be called *R. cimbrica*, *R. teutonica*, and *R. venetiana.* We venture to think, however, that the climax of nomenclatural aberration is reached in such a name as "*Ko-*

ninckina Leopoldi Austriæ nov. spec." Here the author is following the bad example of "*Spiriferina Maximiliani Leuchtenbergensis* Klipstein *sp.*," and similar preciosities of the older writer. If emperors and dukes need such distinctive appellations, what must be done for ordinary mortals? Some day we shall see "*Robinsonia Gulielmi-Smithi-South-Kensingtonensis* Jones *sp.*" Seriously, no amount of snobbishness can make these names binomial. Mr. Bittner will need no apology for these remarks, for he has written:—

> "Es wäre nur zu wünschen, dass man sich auch gegen andere . . . Uebelstände und Missbräuche in der Nomenclatur . . . in so eifriger Weise aussprechen . . . möchte."

In his investigations into the internal structure of some of these Brachiopods the author has received much help from the researches of Mr. H. Zugmayer, many of which are here published for the first time. Like the Rev. Norman Glass, Mr. Zugmayer has devoted much attention to the shape of the lophophoral support. While Mr. Glass, however, works his specimens out by careful dissection, Mr. Zugmayer adopts the fashionable method of cutting a series of sections. Morphologists, as we know, look down on palæontologists, and their real reason is that the latter cannot use the Caldwell microtome; but the figures here published will go far to remove that reproach. One could wish, however, for more diagrams elucidating the results obtained by the sections.

The author has made a large number of new subgenera and a few new genera, the details of which are too technical for reproduction here. The following forms may be noted as strictly characteristic of the Trias:—The Koninckinidæ, especially *Koninckina* and *Amphiclina*; the Thecospiridæ; certain Rhynchonellidæ, viz. *Halorella*, *Dimerella*, and the subgenera *Austriella* and *Norella*; *Camerothyris* and *Cruratula*, which are two subgenera of *Waldheimia*; *Nucleatula* and *Juvavella*, two new genera of the Centronelline type of Terebratulidæ; long-beaked forms of *Retzia*; most of the diplospire *Spirigeræ*; the septate *Spirigeræ* (*Amphitomella*); *Mentzelia*, a subgenus of *Spiriferina*; the doubtful *Badiotella*; and some peculiar *Cyrtinæ*.

Turning now to Part II. of the work, we may note the following details concerning some of the above forms.

The numerous groups of *Spiriferina*, though convenient, are of uncertain value; for it is uncertain whether, in determining affinities, more weight should be attached to the structure of the beak or to the ribbing. Ribbing varies greatly in forms with the same beak-structure, *e.g.* the *Hirsuta* group. This is an instructive instance of the difficulty of classifying on other grounds than those of phylogenesis.

The *Cyrtinæ* are interesting. *C. Fritschii* is a new species in which the pseudo-deltidium, which in other Brachiopods is a single plate closing in the peduncular aperture, consists of two rows of separate scale-like plates alternating with one another. *C. Buchii* and *C. Zittelii* appear to have been attached, at least in youth, by the apex of the larger valve, which is often curiously distorted. This fact may explain the pseudo-deltidium of *C. Fritschii*, for it may have been flexible to allow of the passage of a short peduncle or byssus. These forms lead up to *Cyrtotheca*, which was attached by one of the broad surfaces supporting the beak of the larger valve. The unique original of this genus has unfortunately been lost.

The genus *Spirigera* is divided into numerous groups, many of which have a secondary lamella running alongside of the main lamella that supports the spires of the lophophore; they are therefore said to be "diplospire." This structure is extremely rare in Palæozoic species of the genus.

The Koninckinidæ form the most widely distributed family of the Upper Alpine Trias; and of it, as well as of the four genera belonging to it, a complete description is given. In Mr. Bittner's opinion this family has been shown by the researches of Mr. Zugmayer to be closely allied to the Spiriferidæ. The lophophore support is diplospire. *Amphiclinodonta*, a new genus of this family, has an extremely complicated hinge and teeth.

Badiotella is a remarkable genus founded on a single unsymmetrical large valve. Its resemblance to *Streptorhynchus* suggests that it is probably a relic of the Strophomenidæ.

Juvavella and *Nucleatula* are two new genera of the Centronellinæ found in the Hallstatt limestone. This group has not hitherto been found in rocks of so late an age.

The general relations of the Triassic Brachiopods of the Alps may be summarized as follows:—

In the Lower Trias there are only two species, a *Lingula* and a *Discina*.

In the Muschelkalk there are forty-two species, referable to *Lingula*, *Discina*, *Terebratula*, *Waldheimia*, *Rhynchonella*, *Spirigera*, *Retzia*, *Spiriferina*, and *Mentzelia*. All these, in closely allied or even identical forms, appear again in the Upper Trias.

The Upper Trias contains over 300 species, including all the types already mentioned. This, therefore, is a truer representation of the Brachiopod fauna of the Triassic period. The faunas of the Lower and Middle Trias are less, merely because the conditions were no so favourable in the Alpine area.

In the Triassic fauna hingeless genera are very rare.

Among the hinged genera two families, each containing over 100 species, are noticeable: the Spiriferidæ for the large number of genera, subgenera, and minor groups, combined with a paucity of individuals; the Rhynchonellidæ for the large number of individuals, with few well-marked genera or subgenera. The philosophic naturalist is tempted to suggest that the few divisions recognized in the latter family may be due to the very richness of the material.

The spire-bearers almost exactly equal the non-spire-bearers in the number of species. The latter, however, exceed in individuals, and, from this period onwards, increase in importance, while the spire-bearers soon disappear from the rock record. It is, therefore, very noteworthy that, just before their extinction, the spire-bearers should not only develop new branches—the Koninckinidæ and (?) Thecospiridæ—but should also break up into so many genera, subgenera, and minor groups. A similar efflorescence, as Mr. Bittner observes, marked the later history of the Terebratulidæ, a family now almost extinct.

These facts are certainly opposed to the statement of Hyatt that stems give off numerous forms in their early youth, when the field is free, but not in old age, when they begin to be crowded out by the struggle for existence. Possibly, however, the opposition is more apparent than real, and will disappear when the Brachiopoda shall have been studied under the guidance of modern principles of evolution. Such a study has begun in America, but we regret to see little sign of it in the present work. No doubt Mr. Bittner is only waiting to complete his knowledge, before entering on a field where he will meet with worse obstacles than hard rocks and battered specimens—with illusion and ignorance, prejudice and envy, obstinacy and superstition. When he does start, we shall be the first to wish him good speed.

F. A. BATHER.

A TEXT-BOOK OF POLITICAL ECONOMY.

Elements of Economics of Industry. Being the first volume of "Elements of Economics." By Prof. Alfred Marshall. (London: Macmillan and Co., 1892.)

THE nomenclature of this work reminds us of the ancient custom according to which the alternate generations of a family were named alike. As the son of Hipponicus was called, not after Hipponicus, but after Hipponicus' father, Callias; so the "Economics of Industry," though sprung from the "Principles of Economics," of which it is a miniature, yet does not derive its title from that work, but from the predecessor of that work, the well-known text-book which saw the light some thirteen years ago. The first and the second "Economics of Industry" are unlike in form; but a general family resemblance may be traced between the two generations. A sort of reversion is presented by the circumstance that trades unions are discussed in the latest as in the earliest of our author's books; but not in the intermediate "Principles of Economics." The character of the "Economics of Industry" the younger, and its position in the family group, may best be indicated if, comparing it with its immediate predecessor, the second edition of the "Principles of Economics," we notice what has been retained what has been omitted, and what has been added.

The fundamental principles of political economy as enounced by Prof. Marshall in his *magnum opus*, have been transferred to the pages before us without alteration. The conception of economics as the science of measurable—not necessarily selfish—motives is again the starting-point. Thence we are led to the construction of demand-curves, and that construction by which the benefit which the consumer derives from fall in price is represented. Corresponding to demand-curves and "consumer's rent" are, on the other side of the counter, so to speak, supply-curves and rent proper. But the correspondence is not close, and the diagrammatic representation of the conditions of supply presents peculiar difficulties. It is perplexed by the principles of "increasing" and "decreasing returns." Difficulty is caused by the distinction—first clearly indicated by Prof. Marshall—between "long periods" and "short periods." An effort is required to realize the idea of supply, as it were, projected through time—the vast conception of skilled work put upon a future labour-market by parental providence for vicarious remuneration. The forces of demand and supply determine price, acting simultaneously, in the sense in which equations are called simultaneous. "Just in the same way, when several balls are lying in a bowl, they mutually determine one another's position." The law of demand and supply—the gravitation of the economic system—governs widely distant spheres; not only exchange in the proper narrow sense, but also distribution. Prof. Marshall was, we believe, the first clearly to discern this identity. But, while contemplating the unity of the genus, he has not lost sight of the diversity of the species. No one else has so fully enumerated and allowed for what may be called the *propria* of the different markets; such as the circumstance that many of the disadvantages in bargaining to which the workman is subject are *cumulative.* It is this union of wide general views with minute knowledge of concrete details which imparts peculiar weight to Prof. Marshall's recommendations respecting questions of practical moment, such as the limitation of the hours of labour.

These lessons have now been made easier by the omission of much that is accessory and abstruse in the original volume; in particular, the literary criticisms and the mathematical demonstrations. Among the latter class of omissions two seem conspicuous: the difficult formula for discounting future pleasure, and what may be called the higher theory of the supply-curve, including its possible plural intersection with the demand-curve. Difficult, the present writer may well call these theories, for he has to confess that he was mistaken in some strictures passed upon them in a review of the first edition of the "Principles of Economics" (NATURE, August 14, 1890). The fuller statements about those subjects contained in the second edition made it evident that there had occurred what more frequently occurs than is acknowledged: the author was right, and the critic was wrong. The little incident may be referred to as justifying the plan of abridgment which has been adopted—by omission rather than compression of difficult demonstrations. "It seemed that the difficulty of an argument would be increased rather than diminished by curtailing it and leaving out some of its steps." There results a text-book eminently fitted for the purpose of education, embodying the result of original reflections in a shape adapted to the needs of beginners; complete in itself, yet capable of being supplemented by the judicious teacher who, referring to the "Principles of Economics," may point to that higher world of thought and lead the way.

Practical exigencies have induced Prof. Marshall to forestall the discussion of trade unionism which may be expected in the second volume of the "Principles of Economics." In the work before us he thus states the claim of unions to make economic friction act in favour of the workman:—

> "A viscous fluid in a vessel tends to form a level surface; but, if from time to time an artificial force pushes down the left side, which we may take to correspond to wages, it may reasonably be maintained that the average position of the left side is lower than it would have been without such interference, in spite of the in-

disputable fact that the force of gravitation is constantly tending to reinstate the position of equilibrium. What unions claim to be able to do corresponds to applying frequent and stronger pressure on the right-hand side, thus causing profits to yield the higher level to wages."

To this argument there is opposed a preliminary objection, that friction is not strong in the labour-market, that competition is much more effective than unionists assume. There is wanting, indeed, an exact measure of this friction, as in the case of so many economic forces; one must be content with a rough mean between the divergent statements of experienced persons. The claim on behalf of the unions may now be considered under two heads—with reference to a single trade, and where the union is supposed to be extended to all the trades of a country. But we cannot here follow the subtle argument into all the intricacies of the subject. We shall refer only, or chiefly, to the latter case—which, in view of the developments of the new unionism, cannot be regarded as imaginary—the case of a supposed universal union. The main argument against this sort of unionism is that a rise of wages obtained at the expense of profits tends to cause a diminution, or at least a check to the growth, of those accumulations from which the remuneration of the labourer is derived. "This old argument has both gained and lost strength in recent times." Upon a balance of considerations, it still appears weighty; it is even cumulative, the diminution of the national dividend being progressive from year to year. Two counter-arguments are urged by unionists. First, they claim that through their policy the machinery of the labour-market works more smoothly; thus it saves the employer trouble and anxiety to be able to buy his labour—just as it does to buy his raw material—at wholesale prices (a fixed minimum rate of wage). After a detailed consideration of the policy of trade unions, Prof. Marshall concludes that in some cases—especially where the invigorating effect of foreign competition is felt—"trade unions, on the whole, facilitate business." It is sometimes otherwise with trades which have a monopoly of some special skill. A second great argument in favour of trades unions is that they have increased the efficiency of workmen, thereby increasing the total produce. The beneficial effect on the standard of life is to be admitted in cases like that of the London Docks. "But this answer is not open to those unions or branches of unions that in effect foster dull and unenergetic habits of work." Where reasons are so conflicting, it were to be wished that direct observation were available. But here, as elsewhere in economics, history is difficult to interpret. There is, indeed, the patent fact that those occupations in which wages have risen most in England are those in which there are no unions—namely, the kinds of domestic service and the employments of women for which there has been an increase of demand and a check of supply. On the other hand are urged cases in which higher wages have attended stronger unions. But we cannot be quite certain that the gain of one trade is not obtained at the expense of a greater loss to some other trade. Also prosperity may be rather a cause than a consequence of the prevalence of trades unions. The general conclusion appears to be that unions are not to be condemned or extolled in the abstract, but only after attending to the particular character of each, and considering whether its policy complies with the conditions of success. Where the consequences for good or evil are so widespread, and the issues are to a large extent moral—whether unionists are procuring a small good immediately and for themselves at the expense of a greater loss in the future or to other classes—it is natural to appeal to public sympathy and criticism. "Public opinion, based on sound economics and just morality, will, it may be hoped, become ever more and more the arbiter of the conditions of industry." Among the means of educating public opinion we should place high the study of the "Economics of Industry."

F. Y. E.

OUR BOOK SHELF.

Elements of Materia Medica and Therapeutics; including the whole of the Remedies of the British Pharmacopœia of 1885 *and its Appendix of* 1890. By C. E. Armand Semple, B.A., M.B. (Cantab.), M.R.C.P. Pp. 480. (London: Longmans, Green, and Co., 1892.)

WHEN a knowledge of medical botany was absolutely necessary to the student of materia medica, such works as Pereira's "Elements" and Bentley's "Text-book of Organic Materia Medica" supplied a real want in this direction. But with the altered ideas of modern teaching there is a growing tendency among examiners to demand rather a thorough knowledge of the chemistry and intimate action of the active principles of drugs than of their botanical sources. This being the case, it is a little difficult to understand why the work at present under notice has been written. Mr. Semple thinks that by the aid of his book and of the illustrations contained therein, the student will be able to master the subject, and will have the facts impressed upon him more vividly by the pictures. We think, however, that most will agree with us that one of the already well-known text-books, such as the excellent one by Mitchell Bruce, or the larger and more comprehensive one by Brunton—used in connection with a materia medica museum—will make the subject at least equally interesting, and enable the worker to pass a far better examination. Since the 440 illustrations included in the text appear to be brought forward as the strong point of Mr. Semple's cram-book, we must draw attention to a few of their peculiarities noticeable at a glance. In the first place, non-officinal parts of plants are sometimes illustrated, and not the officinal parts. Again, some of the plates, though good enough in themselves, such as those illustrating the extraction of tar and the collection of asafœtida, narrowly escape being ludicrous in a work on materia medica. Others, such as that showing a sulphuric acid factory, give the student no idea of the principles involved in the processes of preparation, and it is these alone which are of importance to him. Many sketches are evidently inserted simply because the blocks were at hand. Lastly, in the inorganic portion we regret to notice the complete absence of chemical equations and formulæ, without a knowledge of which the student's knowledge is indeed rudimentary.

Elementary Lessons in Heat. By S. E. Tillman, Professor of Chemistry, U.S. Military Academy. Second Edition. (New York: John Wiley and Sons. London: Gay and Bird. 1892.)

THE "Lessons" presented in this volume were originally prepared for the use of students at the U.S. Military Academy. They are well fitted for students who can devote only a limited time to this branch of science, for the author not only knows his subject thoroughly, but understands how to deal with it in a way that shall be readily intelligible. His main object has been to direct attention only to important facts and principles, and to bring out the various links by which they are logically connected with one another. There are eleven chapters, in which he treats of thermometry, dilation of bodies, calorimetry, production and condensation of vapour, change of state, hygrometry, conduction, radiation, thermo-dynamics, terrestrial temperatures, aërial meteors, and aqueous meteors. Few changes have been made in the present edition, but the author has introduced a collection of elementary problems, which, as he says, may be "advantageously solved in connection with the subject-matter to which they appertain."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Aurora.

THERE was a fine aurora visible in this locality on Saturday night, April 23. It was seen at intervals, whenever the clouds broke away, until after midnight. This display is specially interesting, because it forms the continuation of a series of recurrences, at the precise interval of twenty-seven days, which began in December, the dates being as follows: December 9, January 5, February 2, February 29, March 27, and April 23. Some of these displays have been brilliant, and all of them have been well defined. In the table of auroras which I have constructed, based upon a periodicity corresponding to the time of a synodic revolution of the sun—namely, twenty-seven days, six hours, and forty minutes—there was, for several years preceding the sun spot minimum in 1889 and 1890, a return each spring of series of recurrences associated with the same part of the sun as that above described. A corresponding systematic tabulation of the records of solar conditions shows that this association bears a direct relation to reappearances at the eastern limb of an area which has been much frequented by spots and faculæ, and which has been located persistently south of the sun's equator. In like manner there are other areas located in the sun's northern hemisphere which have been much disturbed, and whose reappearances at the eastern limb have been attended year after year by series of recurrences of the aurora, in the autumn months chiefly, if not exclusively. From this it would appear that, in order that a solar disturbance may have its full magnetic effect upon the earth, it is necessary that it should be at the sun's eastern limb, and as nearly as possible in the plane of the earth's orbit. It appears, also, that the disturbances which recur upon certain parts of the sun so persistently year after year have greater magnetic effect than those of comparatively sporadic character located elsewhere.

Lyons, N.Y., April 25. M. A. VEEDER.

The White Rhinoceros.

IN my "Naturalist in the Transvaal" (p. 5), I recently deplored the supposed fact that a perfect skin or skeleton of *Rhinoceros simus* was unknown in any Museum; and I relied for my information on the interesting communication in your columns made by Dr. Sclater (vol. xlii. p. 520).

I have just received a very welcome letter from Dr. Jentink, the Director of the Leyden Museum, stating that there are two skins to be found in that collection, "one in a rather bad state, but the other a beautiful stuffed specimen, measuring more than 3½ metres."

Dr. Jentink had published this information in *Notes from the Leyden Museum* (October 1890), a communication I had not seen when I returned from the Transvaal and wrote on the matter.

This is a most gratifying fact for all zoologists, and the Leyden Museum appears to have a unique treasure.

Purley, Surrey, May 3. W. L. DISTANT.

The Line Spectra of the Elements.

IN Prof. Runge's article on the spectra of the elements in last week's issue of NATURE (p. 607) he refers to my explanation of double lines in the spectra of gases ("Cause of Double Lines in Spectra," Trans. of the Roy. Dublin Soc., vol. iv. 1891, p. 563); and says:—"I do not understand the decomposition of the arbitrary curve" [rather, of the actual motion of the electric charge within the molecules of the gas] "in a series of superposed ellipses" [rather, into a series of pendulous motions in ellipses]. "For the movement is supposed not to be periodical" [rather, is not known to be periodical], "and Fourier's theorem then would not apply, at least the periods of the superposed ellipses would not be definite, as long as there are no data except the arbitrary curve itself" [rather, no data except those furnished by the positions and intensities of the spectral lines].

Prof. Runge will pardon me if I say that this objection seems to me to be of the same kind as a doubt with respect to the value of tables of logarithms on the ground that many logarithms are incommensurable with integer numbers, and therefore cannot equal decimal fractions.

Take, for example, a simple vibratory movement of an electron within the molecules, represented by

$$x = a\sin\left(2\pi\frac{mt}{j}\right) + b\sin\left(2\pi\frac{\pi mt}{j}\right), \quad \ldots \ldots (1)$$

which would give rise to two lines in the spectrum with oscillation-frequencies m and πm in each jot of time. This, Prof. Runge objects, cannot be analyzed by Fourier's theorem, because it is not periodic. But

$$x = a\sin\left(2\pi\frac{mt}{j}\right) + b\sin\left(2\pi\frac{3{\cdot}14159\,mt}{j}\right), \quad \ldots (2)$$

$$x = a\sin\left(2\pi\frac{mt}{j}\right) + b\sin\left(2\pi\frac{3{\cdot}141593\,mt}{j}\right), \quad \ldots (3)$$

$$x = a\sin\left(2\pi\frac{mt}{j}\right) + b\sin\left(2\pi\frac{3{\cdot}1415927\,mt}{j}\right), \quad . \quad (4)$$

&c., &c., &c.,

being periodic, can be so analyzed. The motion represented by the first of these (Equation 2) approximates for a certain time to the actual motion which is represented by Equation 1. The motion represented by the next (Equation 3) approximates more closely and for a longer time; and so on. So that Fourier's theorem can be applied to motions which approximate to the non-periodic motion represented by Equation 1, in any assigned degree and for any assigned time; just as a decimal can approximate in any assigned degree to the value of log 8, although no decimal can equal that logarithm.

G. JOHNSTONE STONEY.

9 Palmerston Park, Dublin, May 1.

On a Proposition in the Kinetic Theory of Gases.

IN last month's *Philosophical Magazine* there is a paper by Lord Rayleigh criticizing a demonstration by Maxwell of the equality of the products $dp_1 \ldots dp_n, dq_1 \ldots dq_n$, and $dP_1 \ldots dP_n, dQ_1 \ldots dQ_n$, where the p's and P's are the momenta, and the q's and Q's the co-ordinates, of a system at the beginning and end of any interval of time.

Lord Rayleigh correctly points out that the assumption of E, the total Energy, as an independent variable, vitiates the proof, and he suggests the substitution of Hamilton's principal function S for the characteristic function A, with t, the time, as an independent variable.

Prof. Boltzmann took a similar objection to Maxwell's demonstration in a paper to the *Philosophical Magazine* in the year 1882, in the course of some comments on my use of the proof in a small treatise on the kinetic theory of gases, and I then privately suggested to him the substitution of S for A, with t independent, as proposed by Lord Rayleigh. But unfortunately, as I now see, the proposition $dp_1 \ldots dq_n = dP_1 \ldots dQ_n$, with t independent, although doubtless true, has no application to the particular problem in the kinetic theory of gases to which I was applying it.

My object was to abbreviate and simplify the proof of a fundamental theorem in the subject originally given by Boltzmann, and which may be fairly well illustrated by the following simple case:—

Suppose that in the plane of a projectile there are two infinite parallel straight lines, A and B, and we introduce such a relation between x_0, y_0, x, and y as will express that when the former is a point on the line A the latter will be a point on B, each of the four quantities x, y, u, v may then be expressed as a function of x_0, y_0, u_0, v_0, and it may be proved that

$$dx\, dy\, du\, dv = \frac{V_0}{V} dx_0\, dy_0\, du_0\, dv_0\,;$$

where V_0 and V are the resolved parts of the projectile's velocity perpendicular to the two lines as it crosses A and B respectively.

For instance, let the lines be vertical $x = a$ and $x = b$, where $b - a = c$. Our equations are—

$$\begin{aligned} x - x_0 = c &= u_0 t \\ y - y_0 &= v_0 t - \frac{gt^2}{2} \\ v &= v_0 - gt \\ u &= u_0 \end{aligned}$$

$$\therefore t = \frac{c}{u_0},\quad v = v_0 - \frac{gc}{u_0},\ u = u_0,\ x = x_0 + c,\ y = y_0 + \frac{v_0 c}{u_0} - \frac{gc^2}{2u_0^2},$$

and

$$\Delta = 1 = \frac{u}{u_0}.$$

Also here $t = \frac{c}{u_0}$ is *not* constant, as it depends upon u_0.

Next let the lines be horizontal, $y = a$, $y = b$, $b - a = c$. We then have

$$\begin{aligned} &(1)\ y - y_0 = c = v_0 t - \frac{gt^2}{2} \\ &(2)\ x - x_0 = u_0 t \\ &(3)\qquad u = u_0 \\ &(4)\qquad v = v_0 - gt. \end{aligned}$$

From (1)

$$t = \frac{v_0 - \sqrt{v_0^2 - 2cg}}{g},\qquad x = x_0 + \frac{u_0}{g}\left(v_0 - \sqrt{v_0^2 - 2cg}\right),$$

$$y = y_0 + c,\qquad u = u_0,\qquad v = \sqrt{v_0^2 - 2cg},$$

and our determinant Δ is

$$\begin{vmatrix} 1, & 0, & \dfrac{v_0 - \sqrt{v_0^2 - 2cg}}{g}, & \dfrac{u_0}{g}\left\{1 - \dfrac{v_0}{\sqrt{v_0^2 - 2cg}}\right\} \\ 0, & 1, & 0, & 0 \\ 0, & 0, & 1, & 0 \\ 0, & 0, & 0, & \dfrac{v_0}{\sqrt{v_0^2 - 2cg}} \end{vmatrix}$$

$$= \frac{v_0}{v}.$$

If our lines were $y = mx$ and $y = mx + c$, our additional condition would be

$$y - y_0 = m(x - x_0) + c\,;$$

and the result mentioned could be arrived at, although with a little additional work.

The actual problem proposed by Boltzmann is the same as this in principle, although of much greater complexity, and it is treated by him with the utmost generality. The important thing here is to show that the S function with t constant is of no application, inasmuch as in both of these very simple illustrations we have t a dependent variable depending upon u_0 or v_0.

I am only pointing out that the S method, with t independent, would not help to establish the particular proposition to which I am referring. It may lead to the determination of a law of permanence of distribution independently of this proposition and by a simpler treatment. The Boltzmann treatment, however, avoids the difficulty which may arise from the fact that *encounters*, whether of finite or infinitely short duration, involve the assumption of discontinuous forces, and, therefore, of a corresponding discontinuity in the form of the S function.

A little consideration shows that the condition E constant cannot lead to any determinate relation between the differential products $dp_1 \ldots dq_n$ and $dP_1 \ldots dQ_n$.

For to take again the simple case of the projectile. Here we get four equations between the nine quantities, $x_0\ y_0\ u_0\ v_0$, $x\ y\ u\ v$ and t, whence it is clear that the elimination of t does not enable us to arrive at more than three equations between the remaining eight quantities, and therefore that we cannot express x, y, u, v separately as determinate functions of $x_0\, y_0\, u_0\, v_0$. To enable us to do this we need one additional condition, and this may be supplied in an infinite number of ways. It may be one of the conditions above considered leading to the equation $dx\, dy\, du\, dv = \frac{V_0}{V} dx_0\, dy_0\, du_0\, dv_0$, or it may be the condition t constant leading to the equality of these differential products, and so forth; but the condition E constant supplies no additional relation between the eight variables. This conclusion holds equally for n degrees of freedom, following from the two partial differential equations in $q_1 \ldots q_n$, $Q_1 \ldots Q_n$, to which the characteristic function A is subject, so that the condition E constant leads to no determinate relation between the differential products.

This conclusion is not inconsistent with Maxwell's proof. That proof takes the form—

$$dp_1 \ldots dq_n = \frac{\Delta}{\Delta'} dP_1 \ldots dQ_n,$$

where Δ is equal to Δ', but it may be proved that in this case Δ and Δ' are separately zero, and therefore that, as stated above, no relation can be established between the two differential products.

H. W. WATSON.

Berkeswell Rectory, Coventry.

Palæonictis in the American Lower Eocene.

PALÆONTOLOGISTS will welcome Dr. T. L. Wortman's discovery of a nearly complete skull of *Palæonictis* in the Wahsatch Lower Eocene of Wyoming. The only specimens of this form known hitherto are the two fragmentary lower jaws from the Suessonian lignites of France upon which De Blainville founded the genus in 1841. This specimen includes the facial region of the skull and the complete lower jaws in fine preservation. We owe it to the expert skill of Dr. Wortman, for the fossil was found completely dissociated; he carried several sacks of the *débris* surrounding the fragments fifteen miles to the nearest river, and by careful washing recovered all the teeth.

The skull is about the size and form of that of the Puma (*Felis concolor*), without the long muzzle so characteristic of all the early Carnivores or Creodonts. The dental series is remarkably compressed and reduced, especially in the upper jaw, the formula being: I $\frac{3}{3}$, C $\frac{1}{1}$, P $\frac{4}{4}$, M $\frac{2}{2}$. The third upper molar has entirely disappeared, the second is as small as the little tubercular in the modern cats, the first is smaller than the fourth premolar. The latter tooth, in conjunction with the first true lower molar, is in course of transformation into a *sectorial*. This and many other features point to the conclusion that *Palæonictis* is closely related to the Eocene ancestors of the Felidæ—which have hitherto been considered a gap in the fossil series.

The type, which we may call *P. occidentalis*, will soon be fully figured and described. HENRY F. OSBORN.

American Museum of Natural History, April 19.

WATERSTON'S THEORY OF GASES.

ON the 11th of December, 1845, a paper by Mr. J. J. Waterston, entitled "On the Physics of Media that are composed of Free and Perfectly Elastic Molecules in a State of Motion," was communicated by Captain Beaufort, R.N., to the Royal Society.

This paper was not published at the time, but was relegated to the Archives. It now, however, has just been issued as a part of the current volume of Philosophical Transactions.

It is preceded by an introduction by Lord Rayleigh, one of the Secretaries of the Royal Society, and we cannot do better—in order to call attention to this remarkable paper, which anticipates the present theories in many respects, and to explain how it is that it now appears—than print Lord Rayleigh's introduction as it stands, and also the introduction to the memoir itself.

"*Introduction by Lord Rayleigh, Sec.R.S.*

"The publication of this paper after nearly half a century demands a word of explanation; and the opportunity may be taken to point out in what respects the received theory of gases had been anticipated by Waterston, and to offer some suggestions as to the origin of certain errors and deficiencies in his views.

"So far as I am aware, the paper, though always accessible in the Archives of the Royal Society, has remained absolutely unnoticed. Most unfortunately the abstract printed at the time (Roy. Soc. Proc., 1846, vol. v. p. 604; . . .) gave no adequate idea of the scope of the memoir, and still less of the nature of the results arrived at. The deficiency was in some degree supplied by a short account in the Report of the British Association for 1851 (. . .), where is distinctly stated the law, which was afterwards to become so famous, of the equality of the kinetic energies of different molecules at the same temperature.

"My own attention was attracted in the first instance to Waterston's work upon the connection between molecular forces and the latent heat of evaporation, and thence to a paper in the *Philosophical Magazine* for 1858, 'On the Theory of Sound.' He there alludes to the theory of gases under consideration as having been started by Herapath in 1821, and he proceeds:—

"'Mr. Herapath unfortunately assumed heat or temperature to be represented by the simple ratio of the velocity instead of the square of the velocity—being in this apparently led astray by the definition of motion generally received—and thus was baffled in his attempts to reconcile his theory with observation. If we make this change in Mr. Herapath's definition of heat or temperature, viz. that it is proportional to the *vis viva*, or square velocity of the moving particle, not to the momentum, or simple ratio of the velocity, we can without much difficulty deduce, not only the primary laws of elastic fluids, but also the other physical properties of gases enumerated above in the third objection to Newton's hypothesis. In the Archives of the Royal Society for 1845-46, there is a paper "On the Physics of Media that consist of Perfectly Elastic Molecules in a State of Motion," which contains the synthetical reasoning upon which the demonstration of these matters rests. The velocity of sound is therein deduced to be equal to the velocity acquired in falling through three-fourths of a uniform atmosphere. This theory does not take account of the size of the molecules. It assumes that no time is lost at the impact, and that if the impact produce rotatory motion, the *vis viva* thus invested bears a constant ratio to the rectilineal *vis viva*, so as not to require separate consideration. It also does not take account of the probable internal motion of composite molecules; yet the results so closely accord with observation in every part of the subject as to leave no doubt that Mr. Herapath's idea of the physical constitution of gases appproximates closely to the truth. M. Krönig appears to have entered upon the subject in an independent manner, and arrives at the same result; M. Clausius, too, as we learn from his paper "On the Nature of the Motion we call Heat" (*Phil. Mag.*, vol. xiv., 1857, p. 108).'

"Impressed with the above passage and with the general ingenuity and soundness of Waterston's views, I took the first opportunity of consulting the Archives, and saw at once that the memoir justified the large claims made for it, and that it marks an immense advance in the direction of the now generally received theory. The omission to publish it at the time was a misfortune, which probably retarded the development of the subject by ten or fifteen years. It is singular that Waterston appears to have advanced no claim for subsequent publication, whether in the Transactions of the Society, or through some other channel. At any time since 1860 reference would naturally have been made to Maxwell, and it cannot be doubted that he would have at once recommended that everything possible should be done to atone for the original failure of appreciation.

"It is difficult to put oneself in imagination into the position of the reader of 1845, and one can understand that the substance of the memoir should have appeared speculative, and that its mathematical style should have failed to attract. But it is startling to find a referee expressing the opinion that 'the paper is nothing but nonsense, unfit even for reading before the Society.' Another remarks 'that the whole investigation is confessedly founded on a principle entirely hypothetical, from which it is the object to deduce a mathematical representation of the phenomena of elastic media. It exhibits much skill and many remarkable accordances with the general facts, as well as numerical values furnished by observation. . . . The original principle itself involves an assumption which seems to me very difficult to admit, and by no means a satisfactory basis for a mathematical theory, viz. that the elasticity of a medium is to be measured by supposing its molecules in vertical motion, and making a succession of impacts against an elastic gravitating plane.' These remarks are not here quoted with the idea of reflecting upon the judgment of the referee, who was one of the best qualified authorities of the day, and evidently devoted to a most difficult task his careful attention; but rather with the view of throwing light upon the attitude then assumed by men of science in regard to this question, and in order to point a moral. The history of this paper suggests that highly speculative investigations, especially by an unknown author, are best brought before the world through some other channel than a scientific Society, which naturally hesitates to admit into its printed records matter of uncertain value. Perhaps one may go further, and say that a young author who believes himself capable of great things would usually do well to secure the favourable recognition of the scientific world by work whose scope is limited, and whose value is easily judged, before embarking upon higher flights.

"One circumstance which may have told unfavourably upon the reception of Waterston's paper is that he mentions no predecessors. Had he put forward his investigation as a development of the theory of D. Bernoulli, a referee might have hesitated to call it nonsense. It is probable, however, that Waterston was unacquainted with Bernoulli's work, and doubtful whether at that time he knew that Herapath had to some extent foreshadowed similar views.

"At the present time the interest of Waterston's paper can, of course, be little more than historical. What strikes one most is the marvellous courage with which he attacked questions, some of which even now present serious difficulties. To say that he was not always successful is only to deny his claim to rank among the very foremost theorists of all ages. The character of the advance to be dated from this paper will be at once understood when it is realized that Waterston was the first to introduce into the theory the conception that heat and temperature are to be measured by *vis viva*. This enabled him at a stroke to complete Bernoulli's explanation of pressure by showing the accordance of the hypothetical medium with the law of Dalton and Gay-Lussac. In the second section the great feature is the statement (VII.), that 'in mixed media the mean square molecular velocity is inversely proportional to the specific weight of the molecules.' The proof which Waterston gave is doubtless not satisfactory; but the same may be said of that advanced by Maxwell fifteen years later. The law of Avogadro follows at once, as well as that of Graham relative to diffusion. Since the law of equal energies was actually published in 1851, there can be no hesitation, I think, in attaching Waterston's name to it. The attainment of correct results in the third section, dealing with adiabatic expansion, was only prevented by a slip of calculation.

"In a few important respects Waterston stopped short. There is no indication, so far as I can see, that he recognized any other form of motion, or energy, than the translatory motion, though this is sometimes spoken of as vibratory. In this matter the priority in a wider view rests with Clausius. According to Waterston the ratio of specific heats should be (as for mercury vapour) 1·67 in all cases. Again, although he was well aware that the molecular velocity cannot be constant, there is no anticipation of the law of distribution of velocities established by Maxwell.

"A large part of the paper deals with chemistry, and shows that his views upon that subject also were much in advance of those generally held at the time.

"The following extract from a letter by Prof. McLeod will put the reader into possession of the main facts of the case:—

"'It seems a misfortune that the paper was not printed when it was written, for it shadows forth many of the ideas of modern chemistry which have been adopted since 1845, and it might have been the means of hastening their reception by chemists.

"'The author compares the masses of equal volumes of gaseous and volatile elements and compounds, and taking the mass of a unit volume of hydrogen as unity, he regards the masses of the same volume of other volatile bodies as representing their molecular weight, and in the case of the elements he employs their symbols to indicate the molecules.

"'In water he considers that the molecule of hydrogen is combined with half a molecule of oxygen, forming one of steam, and he therefore represents the compound as $HO_{\frac{1}{2}}$. He does not make use of the term "atom" (although he speaks of atomic weight on p. 18, but thinks it divisible), and if he had called the smallest proportion of an element which enters into combination an atom, he would probably have been led to believe that the molecules of some of the simple bodies contain two atoms, and he might have adopted two volumes to represent the molecule, as is done at the present time. The author calls one volume or molecule of chlorine Cl, one volume or molecule of hydrogen H, and one volume or molecule of hydrochloric acid $H_{\frac{1}{2}}Cl_{\frac{1}{2}}$. If he had regarded the molecules as containing two indivisible atoms, these bodies would have been represented, as now, by the formulæ Cl_2, H_2, and HCl respectively, all occupying two volumes. § 15 shows how near he was to this conception. Gerhardt, in the fourth part of his "Traité de Chimie Organique," published in 1856, points out the uniformity introduced into chemical theory by the adoption of this system.

"'For carbon he makes C = 12, as now accepted, although I do not find how he arrives at this number. He seems to have anticipated one of Ramsay's recent discoveries, that nitrous anhydride (hyponitrous acid, $ON_{\frac{2}{3}}$, No. 26 in the table) dissociates on evaporation into nitric oxide (binoxide of nitrogen, No. 23) and nitric peroxide (nitrous acid, No. 25).

"'The values for the symbols for sulphur, phosphorus, and arsenic, taken from the vapour densities (and which are multiples of what are believed to be the true atomic weights), cause some complexity in the formulæ of their compounds.

"'There seem to be errors in the formulæ of alcohol and ether on p. 49, for they do not agree with those in the table. They ought probably to be written

$$2(HC_{\frac{1}{2}}) + O_{\frac{1}{2}}2H_{\frac{1}{2}} \text{ and } 4(HC_{\frac{1}{2}}) + O_{\frac{1}{2}}2H_{\frac{1}{2}}.$$

"'Considering how nearly Waterston approached what is now believed to be the true theory, it is disappointing to read his controversy with Odling in 1863 and 1864 (*Phil. Mag.*, vols. xxvi. and xxvii.), where he seems to oppose the new formulæ then being introduced. He is very dogmatic about the constitution of hydrate of potash: he very properly insists that we can only obtain a knowledge of the molecular weight of bodies that can be volatilized, and of which the vapour densities can be determined, but he does not see the analogy between the hydrate and oxide of potassium with alcohol and ether, probably because he regards these latter bodies as combinations of water with different quantities of olefiant gas. He writes water $HO_{\frac{1}{2}} = 9$, alcohol $CH_2HO_{\frac{1}{2}} = 23$, and ether $C_2H4 . HO_{\frac{1}{2}} = 37$, whilst he considers potassic hydrate $KO_{\frac{1}{2}} . HO_{\frac{1}{2}} = 56$, and oxide of potassium $KO_{\frac{1}{2}} = 47$, the hydrate having a higher molecular weight than the oxide. If we regard these compounds as derived from water by the replacement of hydrogen by ethyl and potassium respectively, the analogy between the two series is complete (ethyl was discovered in 1849, and is mentioned by Waterston).

$$\begin{array}{rlrl} H_2O & = 18 & H_2O & = 18. \\ (C_2H_5)HO & = 46 & KHO & = 56. \\ (C_2H_5)_2O & = 74 & K_2O & = 94. \end{array}$$

"'From a remark in the *Phil. Mag.* (vol. xxvi. p. 520), I imagined that Waterston had arrived at the double atomic weights of many of the metals now adopted, for he gives that of iron as 56 and that of aluminium as 27, calculated from their specific heats, but there is an error in his arithmetic, for 3·3 divided by the specific heat of iron ·1138 gives 28·998, and 3·3 divided by the specific heat of aluminium ·2143 gives 15·399.'

"With the exception of some corrections relating merely to stops and spelling, the paper is here reproduced exactly as it stands in the author's manuscript.—December 1891."

The author's own introduction to his memoir, which occupies eighty pages of the Philosophical Transactions as now printed, runs as follows:—

"Of the physical theories of heat that have claimed attention since the time of Bacon, that which ascribes its cause to the intense vibrations of the elementary parts of bodies has received a considerable accession of probability from the recent experiments of Forbes and Melloni. It is admitted that these have been the means of demonstrating that the mode of its radiation is identical with that of light in the quantities of refraction and polarization. The evidence that has been accumulated in favour of the undulatory theory of light has thus been made to support with a great portion of its weight a like theory of the phenomena of heat; and we are, perhaps, justified in expecting that the complete development of this theory will have a much more important influence on the progress of science, because of its more obvious connection and intimate blending with almost every appearance of Nature. Heat is not only the subject of direct sensation and the vivifier of organic life, but it is manifested as the accompaniment of mechanical force. It is related to it both as cause and effect, and submits itself readily to measurement by means of the mechanical changes that are among the most prominent indications of its change of intensity. The undulatory theory at once leads us to the conclusion that, inasmuch as the temperature of a body is a persistent quality due to the motion of its molecules, its internal constitution must admit of it retaining a vast amount of living force. Indeed, it seems to be almost impossible now to escape from the inference that heat is essentially molecular *vis viva*. In solids, the molecular oscillations may be viewed as being restrained by the intense forces of aggregation. In vapours and gases these seem to be overcome; vibrations can no longer be produced by the inherent *vis insita* of the molecules struggling with attractive and repellent forces; the struggle is over and the molecules are free; but they, nevertheless, continue to maintain a certain temperature; they are capable of heating and being heated; they are endowed with the quality heat, which, being of itself motion, compels us to infer that a molecule in motion without any force to restrain or qualify it, is in every respect to be considered as a free projectile. Allow such free projectiles to be endowed with perfect elasticity, and likewise extend the same property to the elementary parts of all bodies that they strike against, and we immediately introduce the principle of the conservation of *vis viva* to regulate the general effects of their fortuitous encounters. Whether gases do consist of such minute elastic projectiles or not, it seems worth while to inquire into the physical attributes of media so constituted, and to see what analogy they bear to the elegant and symmetrical laws of aëriform bodies.

"Some years ago I made an attempt to do so, proceeding synthetically from this fundamental hypothesis, and have lately obtained demonstration of one or two points where the proof was then deficient. The results have appeared so encouraging, although derived from very humble applications of mathematics, that I have been led to hope a popular account of the train of reasoning may not prove unacceptable to the Royal Society.—September 1, 1845."

REPORT OF THE ROYAL SOCIETY'S COMMITTEE ON COLOUR VISION.

A COMMITTEE, consisting of Lord Rayleigh as Chairman, Lord Kelvin, Mr. Brudenell Carter, Prof. Church, Mr. J. Evans, Dr. Farquharson, M.P., Prof. Michael Foster, Mr. Galton, Dr. Pole, Sir G. Stokes, and Captain Abney, as Secretary, was appointed by the Council of the Royal Society in March 1890, to consider the question of testing for defective colour vision. Their report has just been presented to the Royal Society, and it possesses great practical interest for all classes, considering that on the average one male out of every twenty-five suffers more or less from this form of blindness.

The Committee have taken evidence as to the tests in general use on the railways, and also as to those which have been for some time adopted by the Board of Trade for the mercantile marine service, and have supplemented it by carrying on practical examinations on their own account. Experts have also given evidence as to the different forms of colour-blindness to be found, and the fact that it may be induced by disease as well as be congenital has been brought prominently forward by Dr. Priestley Smith, of Birmingham, and Mr. Nettleship, of St. Thomas's Hospital, and we have it on their authority that this type is not a negligible one. As an outcome of their investigations, the Committee have unanimously agreed to the following recommendations:—

(1) That the Board of Trade, or some other central authority, should schedule certain employments in the mercantile marine and on railways, the filling of which by persons whose vision is defective either for colour or form, or who are ignorant of the names of colours, would involve danger to life and property.

(2) That the proper testing, both for colour and form, of all candidates for such employments should be compulsory.

(3) That the testing should be intrusted to examiners certificated by the central authority.

(4) That the test for colour vision should be that of Holmgren, the sets of wools being approved by the central authority before use, especially as to the correctness of the three test colours, and also of the confusion colours. If the test be satisfactorily passed, it should be followed by the candidate being required to name without hesitation the colours which are employed as signals or lights, and also white light.

(5) That the tests for form should be those of Snellen, and that they should be carried out as laid down in Appendix VI. It would probably, in most cases, suffice if half normal vision in each eye were required.

(6) That a candidate rejected for any of the specified employments should have a right of appeal to an expert approved by the central authority, whose decision should be final.

(7) That a candidate who is rejected for naming colours wrongly, but who has been proved to possess normal colour vision, should be allowed to be re-examined after a proper interval of time.

(8) That a certificate of the candidate's colour vision and form vision according to the appointed tests, and his capacity for naming the signal colours, should be given by the examiner; and that a schedule of persons examined, showing the results, together with the nature of the employments for which examinations were held, should be sent annually to the central authority.

(9) That every third year, or oftener, persons filling the scheduled employments should be examined for form vision.

(10) That the tests in use, and the mode of conducting examinations at the different testing stations, should be inspected periodically by a scientific expert, appointed for that purpose by the central authority.

(11) That the colours used for lights on board ship, and for lamp signals on railways, should, so far as possible, be uniform, and that glasses of the same colour as the green and red sealed pattern glasses of the Royal Navy, should be generally adopted.

(12) That in case of judicial inquiries as to collisions or accidents, witnesses giving evidence as to the nature or position of coloured signals or lights should be themselves tested for colour and form vision.

These recommendations have been framed after duly weighing all the evidence they have collected, and from the results of the experiments they have carried out during the last two years; and the reasons for adopting them are set forth at some length in the report. The Committee have, perhaps wisely, refused to endorse any particular hypothesis of colour vision, though they have described two, those of Young and Hering, in some detail, no doubt considering that everything which might be debatable had better be avoided when practical recommendations alone were in question. It is, however, a matter of some regret that this should be the case, as a Committee so strongly constituted should have been able, if not to convince every one, at least to lead opinion into proper channels. What little they have said in the notes to the report leads one to suspect that they are not satisfied that either Young or Hering has given a theory which will satisfy all requirements. Leaving, however, the question of theory, we may point out that the practical necessity of insisting, on the grounds of public safety, that certain posts on railways and on board ship should only be filled by persons possessing normal colour vision, no sane man would call in question. The peril that must arise, for instance, if an engine-driver could by any possibility mistake a red signal of danger for a green signal of safety, or if a look-out man on board ship should be liable to make a similar error, is self-evident; and it is to prevent any such risks being run that the Committee buckled to the task of recommending tests which should be efficient and perfectly trustworthy. There has been for a long time a suspicion, if not more than a suspicion, that the examinations carried on for colour vision by the Board of Trade in the mercantile marine were inadequate in both respects; and what little was known regarding the tests employed by the various railway companies engendered the same feeling of distrust, in those who had considered the subject in a scientific spirit. The evidence shows that the Board of Trade examiners have passed on a second or third examination candidates who have been rejected on their first trial. This is a proof of one of two things: (1) either that the tests employed were bad, or else that colour-blindness had been cured or mitigated. There is no evidence to show that congenital colour-blindness is curable; in fact, what there is is in exactly the contrary direction. For although it is true that reds and greens may be correctly named by a colour-blind person, by making him notice certain slight difference in the intensity or purity of the one colour which represents both of these to him, yet no amount of education or coaching would enable him to distinguish between them under the varying atmospheric conditions under which the signals are seen. The Committee had practical trials of various tests made before them at Swindon and elsewhere, with the result that the Board of Trade tests for the mercantile marine allowed several individuals to be passed as possessing normal colour vision whom other tests distinctly proved to be markedly and probably dangerously colour-blind. Under these circumstances it is not surprising that they have condemned such a system of testing, more especially as it is one which necessitates the naming of colours, and recommend those of Holmgren, which have long given practical proof of their ability to discriminate between normal and even slightly defective colour-perception.

The Holmgren test consists in requiring a candidate to select from a large assortment of wools those colours which appear to him to match a skein of pale yellowish green, a pale pink, and a bright crimson. These pale colours are sure to be matched by the colour-blind with colours which are totally different in hue, and the nature of the mistakes made infallibly indicate the character and danger of the blindness.

The evidence shows that some railways have been under the impression that they were using the Holmgren test, but when the colours were examined critically it was found that the hues of the test-skeins of wool were perfectly different from those determined by the distinguished Swedish investigator. If the two trial test-colours of Holmgren were more brilliant and of rather different hues, it is quite possible that persons with defective colour sense might make correct matches, and pass an examination which they really never should do. It is for this reason that the Committee recommend that the standard test-colours should be officially passed by an expert attached to the Board of Trade, as also those colours with which the colour-blind would most probably match them.

There are several of the recommendations which are especially valuable; for instance, that one by which the test should only be intrusted to examiners certified as competent to conduct the examinations. It is obvious that to have an efficient examination, not only should the test be efficient, but also the examiner. We have heard of a railway foreman being armed with a variegated bunch of wools, and insisting on candidates for employment naming them, and rejecting those who failed to give the name which he considered should be given. Such a test by such an examiner is evidently useless and cruel. The right of appeal by the rejected candidates is also wholesome, though it will probably be very rarely exercised; and as the tribunal to whom such an appeal can be carried is an expert, we may be certain that substantial justice will be meted out.

The whole report is valuable, but the labour will be thrown away unless legislative measures are taken to render it effective. It is no use telling railways what they ought to do, but only what they *must* do, in such examinations as are in question. The subject of colour vision is one which is so open to fads that the public require to be safeguarded from faddists who might happen to have ear of Boards of Directors or general managers; for this reason we hope that reasonable legislative action may be taken within a reasonable time.

THE GREAT EARTHQUAKE IN JAPAN, 1891.[1]

WHILE the occurrence of a great earthquake in a district intersected by railways, and traversed by telegraph wires, brings forcibly before the mind—even of the most casual reader of newspaper reports—the awful and destructive results of such a catastrophe, the scientific man cannot fail to note that it is under such conditions as these the best opportunities will be found for obtaining the necessary data upon which to reason concerning these terrible and still little understood movements of the earth's crust. In connection with the Seismological Society of Japan, a system of reporting the times and chief features of earthquake-shocks has been for some years in successful operation, and all station-masters and Post Office agents are required to transmit their records to a central office; the electrical control of the clocks of course giving these reports a value which they would not otherwise possess.

Two considerable earthquakes in recent years have occurred in areas where it was possible to obtain a great mass of accurate time and other observations, and these can scarcely fail to be of great value to the seismologist. The terrible earthquake of Charleston, on August 31, 1886, was felt over a great part of the United States; and at the railway stations, post offices, and other places where the accurate time was kept, many valuable observations were made. The vast mass of material collected has been dealt with by Prof. Simon Newcomb and Captain C. E. Dutton; and from the Report published by the United States Geological Survey, some remarkable and striking conclusions regarding the rate of movement of earthquake waves would appear to have been established. The Gifu or Ai-Gi earthquake of October 1891 has yielded data which the able seismologists of Japan may be trusted to make the fullest use of, when sufficient time has elapsed for the comparison and discussion of the reports.

As a preliminary notice and striking memorial of the catastrophe, the beautiful volume now before us will be gladly welcomed. The book consists of twenty-nine permanent photographic plates, printed on excellent paper, and forty-six pages of letterpress. The energetic authors of the book were on the scene of the earthquake immediately after its occurrence, and all the plates, except three, are reproductions of photographs taken by Prof. Burton for the Imperial University. It is difficult to realize that the collection of the materials for this handsome book, with the execution of its luxurious typography, illustrations, and binding have been all completed within the short space of two months, and it says much for the enterprise and activity of the Japanese publishers, as well as of the authors, that such a result should have been possible.

One of the most striking effects of the Charleston earthquake, as described in Captain Dutton's report, was the twisting laterally of the permanent way on railway lines. On Plate x. of the work before us a similar serpentine twisting of the railway, suggesting a permanent compression in the line of the rails, is shown to have been effected, and the photograph constitutes a beautiful permanent record of the result. Still more striking are the phenomena displayed at some of the railway bridges, especially that of Nagara Gawa, which is very fully illustrated in Plates xxii., xxiii., xxiv., xxv., and xxvi. Our illustration is a reproduction of one of these plates. Not only have the lattice-work sections of the bridge been snapped asunder, but the great tubular piers have been thrust through the floor on which the railway lines are laid, these latter being forced up in great curves. Many of these photographs tell, incidentally, a very sad story of the loss and suffering endured by the people of the district.

---

[1] "The Great Earthquake in Japan." By John Milne, F.R.S., Professor of Mining and Geology, and W. K. Burton, C.E., Professor of Sanitary Engineering, Imperial University of Japan. With Plates by K. Ogawa. (Yokohama, Japan: Crawford and Co. London: E. Stanford, 1892.)

In the short descriptive remarks which accompany the plates, Prof. Milne has succeeded in giving us much valuable information concerning the earthquake. The Gifu plain is situated about the centre of the Japanese Empire, and consists of a thick alluvial deposit resting on metamorphic rocks, the district being highly cultivated and thickly populated. The severely shaken district, in which complete destruction of buildings and engineering works occurred, measured 4200 square miles, but the effects were felt over an area of 92,000 square miles; and ten thousand people lost their lives, while fifteen thousand were wounded. The earthquake is believed to have originated in the Mino Mountains; but it was in the soft alluvial plain adjoining that the earth-movements were most severely felt. The district thus violently affected supported a population of about 800 to the square mile. Earthquakes have been recorded as occurring in this area, which lies quite away from any volcanic centres, in 1826, in 1827, in 1859, and in 1880; and during the last ten centuries there have been many terrible catastrophes affecting this area which are noticed in the Japanese records.

We look forward with much interest to the publication of the full account of this destructive, and in many respects remarkable, display of seismic energy, which is promised to us by the Professors of the Imperial University of Japan.

J. W. J.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following fifteen candidates were selected on Thursday last (May 5) by the Council of the Royal Society to be recommended for election into the Society. The ballot will take place on June 2, at 4 p.m. We print with the name of each candidate the statement of his qualifications.

Robert Young Armstrong, Lieut.-Colonel R.E.,

From 1870 to 1875 was Assistant Instructor in Submarine Mining and Electricity, and from 1875 to 1882 was Instructor. From 1884 to the present date, Inspector of Submarine Defences of the United Kingdom, Military Ports, and Coaling Stations. From June 1883 to December 1888, adviser to the Board of Trade in electrical matters connected with the Electric Lighting Acts. Was connected with the development of the present apparatus and electrical and mechanical processes employed in submarine mining, and with the compilation of the army instructional books and methods on electricity and submarine mining since 1870. Distinguished as an electrical engineer. It may be said that the present satisfactory state of defensive torpedo warfare in this country is very largely due to his ability and energy.

Frank Evers Beddard, M.A. (Oxon.),

Lecturer on Comparative Anatomy, Guy's Hospital. Prosector to the Zoological Society. Author of the following papers:—"Report on the Isopoda, collected by H.M.S. *Challenger*" (Parts xxxiii., xlviii.); "Nephridia of Acanthodrilus and of Perichæta" (Proc. Roy. Soc., 1886–87); "Structure of Megascolea" (Trans. Roy. Soc. Edin., 1883); "Minute Anatomy of the Ovary of Echidna"; "Subdivision of the Cœlom in Birds and Reptiles" (Proc. Zool. Soc., 1886–88); "Visceral and Muscular Anatomy of Scopus" (*ibid.*, 1885); "Anatomy of various little-known Types of Birds" (*ibid.*) With other papers on Comparative Anatomy in *Ann. and Mag. Nat. Hist.*, *Ibis*, and *Quart. Journ. Micros. Sci.*

John Ambrose Fleming, M.A. (Camb.),

D.Sc. (Lond.). Professor of Electrical Engineering in University College, London. Late Fellow of St. John's College, Cambridge. Fellow of University College, London. Some time Demonstrator in Applied Mechanics in the University of Cambridge. Author of the following papers, among others:—"The Polarisation of Electrodes in Water free from Air" (Proc. Phys. Soc., 1874); "A New Form of Resistance

Balance" (Proc. Phys. Soc., 1880); "On the Characteristic Curves and Surfaces of Incandescent Lamps"; "On Molecular Shadows in Incandescent Lamps"; "On the Use of Daniell's Cell as a Standard of Electromotive Force"; and "Problems in the Distribution of Electric Currents in Networks of Conductors" (Proc. Phys. Soc., 1885); "On the Necessity for a National Standardising Laboratory for Electrical Instruments" (Proc. Inst. Elect. Engs., 1885); "A Design for a Standard of Electrical Resistance" (Proc. Phys. Soc., 1889); "On Electric Discharge between Electrodes at different Temperatures in Air and in High Vacua" (Proc. Roy. Soc., 1889); "On Some Effects of Alternating Current Flow in Circuits having Capacity and Self-induction" (Proc. Inst. Elect. Engs., 1891). Delivered Friday Evening Discourses at the Royal Institution in 1890-91. Author of "Short Lectures to Electrical Artisans," four editions; and of "The Alternate Current Transformer in Theory and Practice."

CLEMENT LE NEVE FOSTER, D.Sc. (Lond.),

F.G.S., Professor of Mining in the Royal College of Science, and H.M. Inspector of Mines. A.R.S.M. He is distinguished for his knowledge of mining in its various scientific aspects; and is the author of numerous papers bearing on Geology, Mineralogy, and Mine-engineering. He has carried on explorations and mining works in Italy, Egypt, and Venezuela, and was for some years a Member of the Geological Survey of England and Wales, in connection with which he made important discoveries bearing on the question of the denudation of the Weald. His papers are published in the Journals of the Geological and Statistical Societies, and other journals.

HANS GADOW, Ph.D. (Jena),

Hon. M.A. Cantab. Strickland Curator and Lecturer on the Advanced Morphology of Vertebrata in the University of Cambridge. A naturalized British subject, engaged in research in Animal Morphology. Author of "Versuch einer vergleichenden Anatomie des Verdauungssystemes der Vögel" (Inaugural Dissertation, *Jenaische Zeitschr.*, xiii., 1879); "Zur vergleichenden Anatomie der Musculatur der Beckens und der hinteren Gliedmasse der Ratitæ" (4to, Jena, 1880, 5 plates); "Untersuchungen über die Bauchmuskeln der Krokodile, Eidechsen und Schildkröten" (*Morphol. Jahrb.*, vii., p. 57); "Beiträge zur Myologie der hinteren Extremität der Reptilien" (*ibid.*, p. 329); "Observations on Comparative Myology" (*Journ. of Anat.*, 1882, p. 493); "Catalogue of Birds in the British Museum" (vols. viii. and ix.); "On the Colours of Feathers as affected by their Structure" (Zool. Soc. Proc., 1882, p. 409); "On the Reproduction of the Carapace in Tortoises" (*Journ. of Anat.*, 1886, p. 220); "On the Cloaca and Copulatory Organs of Amniota" (Phil. Trans., 1887); "On the Modifications of the First and Second Visceral Arches, with Especial Reference to the Homologies of the Auditory Ossicles" (Phil. Trans., 1888); Volume "Aves" in Bronn's "Klassen und Ordnungen des Theirreichs" (in publication). Conjointly with Dr. Gaskell:—"On the Anatomy of the Cardiac Nerves in certain Cold-blooded Vertebrates" (*Journ. of Physiol.*, v.); "Suctorial Apparatus of the Tenuirostres (1883); "On the Anatomical Differences in the Three Kinds of Rhea" (1885); "On some Points in the Anatomy of *Pterocles arenarins*, with remarks on its Systematic Position (1882). "Introduction to the Osteology of the Mammalia," by W. H. Flower, F.R.S., third edition revised with the assistance of Hans Gadow (1885).

ROBERT GIFFEN, LL.D. (Glasc.),

Assistant Secretary (Commercial Department) Board of Trade. Author of "Stock Exchange Securities: an Essay on General Causes of Fluctuation of their Price" (1878); "Essays in Finance," 1st series (1879), 2nd series (1885); "The Growth of Capital" (1889); also of numerous papers communicated to the British Association, Statistical Society, Bankers' Institute, &c. As head of the Statistical Department of the Board of Trade (since incorporated with the Commercial Department) has been examined by Royal Commissions and Parliamentary or Treasury Committees on the following subjects (among others): Depreciation of Silver (1876); Hall Marking; Wine Duties; Agricultural Depression; Trade Depression; Stock Exchange; Gold and Silver; Channel Tunnel; Emigration and Immigration; Corn Averages, &c. Has given great attention to the theory and practice of the use of Index Numbers in the study of Prices and their history, and first invented and used the plan of an Index Number of a purely objective and not an arbitrary character, especially one based on the actual proportion of the different articles of Import and Export to the total. Has explained with regard to numerous branches of statistics, such as imports and exports, the condition and nature of the data, and the way in which they can be used in public discussions. Has also explained in numerous papers the way in which common statistics can be used in stating and solving problems for the politician, *e.g.* statistics of the growth of population, of the growth of incomes and capital. Has also given attention to the problems relating to the incidence of taxation, upon which several papers are included in the "Essays in Finance." Author of numerous official reports, including reports on wages, prices of imports and exports, emigration, &c.

FRANCIS GOTCH, M.R.C.S.,

B.A., B.Sc. (Lond.), Hon. M.A. (Oxon.). Has made researches of value into the physiology of the nervous system, and is the author of the following papers:—"On the Electromotive Properties of the Electrical Organ of Torpedo" (Phil. Trans., 1887, B., p. 487, and 1888, B., p. 329); "On the Electrical Organ of the Skate," with Dr. Burdon Sanderson, F.R.S. (*Journ. of Physiol.*, vol. ix., p. 137, and vol. x., p. 259); "On the Electromotive Changes in the Mammalian Spinal Cord following Electrical Excitation of the Cortex Cerebri," with Prof. Horsley, F.R.S. (Roy. Soc. Proc., vol. xlv., p. 18); as well as of other shorter papers on similar subjects.

WILLIAM ABBOTT HERDMAN, D.Sc.,

F.R.S.E., F.L.S. Professor of Natural History in University College, Liverpool. Distinguished as a Zoologist, and especially for researches into the structure and relations of the Tunicata. Author of the following, amongst other papers:—"Report on the Tunicata of the *Challenger* Expedition," Parts I., II., and III. (*Challenger* Rept., Zool., vol. vi., 1892; vol. xiv., 1886; vol. xxvii., 188); "On the Invertebrate Fauna of Lamlash Bay" (Roy. Phys. Soc. Edin. Proc., vol. v., 1879, and vol. vi., 1880); "On the Olfactory Tubercle, &c., in Simple Ascidians" (*ibid.*, 1881); "On Individual Variations in the Branchial Sac of Ascidians" (Linn. Soc. Journ., vol. xv., 1881); "The Hypophysis Cerebri in Tunicata and Vertebrata" (Roy. Soc. Edin. Proc., 1883): "Report on the Tunicata of the *Triton* Expedition" (Roy. Soc. Edin. Trans., vol. xxxii., 1883); "Report on the Tunicata of the *Lightning* and *Porcupine* Expeditions" (*ibid.*, 1884); "On the Phylogeny of the Tunicata" (Roy. Soc. Edin. Proc., 1885-86;) "On the Structure of Sarcodictyon" (Roy. Phys. Soc. Edin. Proc., 1884); "On the Structure and Functions of the Cerata or Dorsal Papillæ in some Nudibranchiate Mollusca" (*Quart. Journ. Micros. Sci.*, 1890); and of important Reports on the Fauna of Liverpool Bay, 1886-90.

FREDERICK WOLLASTON HUTTON, Captain, R.E.,

Professor of Geology in Canterbury College. F.G.S., C.M.Z.S., Cor. du Mus. d'Hist. Nat. Paris, Cor. Mem. Roy. Soc. Tas., Hon. Mem. Roy. Soc. N.S.W., Cor. Acad. Nat. Sci. Philad., Cor. Ornith. Ver. Wien., Cor. K. K. Geol. Reichsanst. Wien. Author of numerous reports, papers, &c., published by the New Zealand Government, the Geological and Zoological Societies, the New Zealand Institute, &c., and in the *Phil. Mag.* Amongst them are:—"Fishes of New Zealand," 1872; "Geology of the Thames Gold Field (Government Report, 1868-69); "Sketch of the Geology of New Zealand" (Quart. Journ. Geol. Soc.); "Birds inhabiting the Southern Ocean" (*Ibis*, 1865); "On *Peripatus N. Zealandiæ*"; "On the Structure of *Amphibola avellana*"; "Origin of the Fauna and Flora of New Zealand" (*Ann. and Mag. Nat. Hist.*); "Eruptive Rocks of New Zealand," Oscillations of the Earth's Surface (Aust. Assoc. Advt. Sci., 1889); "On Dimensions of Dinornis Bones" (Trans. N. Z. Inst.); "New Zealand Land Shells"; "Revision of the Land Mollusca of New Zealand" (*ibid.*, vol. xvi.). Author of a Class-book of Geology, and of Zoological Exercises for Students in New Zealand. Author of eleven papers in Proc. Linn. Soc. N.S.W. Has done much valuable work in other ways for the advancement of science in New Zealand.

JOHN JOLY, M.A.,

Assistant to the Professor of Civil Engineering in the University of Dublin. Has discovered (*a*) by direct measurement a variation of specific heat at constant volume of various gases with density; (*b*) Iolite in the Granites of Leinster; (*c*) a heterogeneous Beryl Felspar mineral; (*d*) the reversal of *Oldhamia antiqua* and *radiata* impressions in the Slates of Bray Head. Is the author, amongst other papers, of the following:—"On the direct experimental determination of Specific Heats of Gases at Constant Volume" (Proc. Roy. Soc., vol. xlviii., in abstract, recommended for Phil. Trans.); "On the Method of Condensation in Calorimetry" (Proc. Roy. Soc., vols. xlv. and xlvii.); "On the Specific Heats of Minerals" (*ibid.*, vol. xli.); "Observations of Spark Discharge over Surfaces of Dielectrics" (*ibid.* vol. xlvii.); "On the Volcanic Ash of Krakatoa" (Proc. Roy. Dubl. Soc., vol. iv.). Has invented (*a*) the Method of Steam Calorimetry (Trans. and Proc. Roy. Soc., as above); (*b*) a Diffusion Photometer (*Phil. Mag.*, July 1888); (*c*) a Hydrostatic Balance (*ibid.*, Sept. 1888); (*d*) an Instrument for measuring Melting and Boiling Points of Solids, &c., up to a very high temperature (NATURE, vol. xxxiii., and *Industries*, vol. vi.); (*e*) a Method of measuring the Density of a Gas (*Phil. Mag.*, vol. xxx.); (*f*) a Method of reading Distant Meteorological Instruments (Proc. Roy. Dubl. Soc., vol. iv.); (*g*) a Method of measuring Specific Gravities of Minute Quantities of Porous and other Solids (*Phil. Mag.*, July 1888.

JOSEPH LARMOR, M.A.,

D.Sc. Fellow of St. John's College, Cambridge. University and College Lecturer in Mathematics. Senior Wrangler, 1880. Formerly Professor of Mathematics Queen's College, Galway. Fellow of the Royal University of Ireland. Examiner in Mathematics at the University of London. Author of the following papers:—"Application of Generalized Space Coordinates, Potentials, and Isotropic Elasticity" (Trans. Camb. Phil. Soc., vol. xiv.); "Least Action" (Proc. Lond. Math. Soc., vol. xv.); "Flow of Electricity in Linear Conductors" (*ibid.*, vol. xvi.); "Characteristics of an Asymmetric Optical Combination" (*ibid.*, vol. xx.); "Electro-magnetic Induction in Conducting Sheets and Solid Bodies" (*Phil. Mag.*, 1884); and other papers on Pure and Applied Mathematics.

LOUIS C. MIALL,

Professor of Biology in the Yorkshire College. Prof. Miall has published the following papers and books:—Reports on Labyrinthodonts (Rep. Brit. Assoc., 1873-74): the first translated as introduction to S. Anton Fritsch's "Fauna der Permformation Böhmens"; Fossil Teeth of Ceratodus (Palæont. Indica): Sirenoid and Crassopterygian Ganoids, Part I. (Palæont. Soc.); papers on Labyrinthodonts, Rhizodus, Ctenodus, and Megalichthys (Quart. Journ. Geol. Soc.): Studies in Comparative Anatomy: I. Skull of Crocodile, II. Anatomy of the Indian Elephant (jointly with F. Greenwood), III. The Cockroach (jointly with H. Denny); Vertebrate Palæontology in Geol. Record (Sub-editor). In 1875 received the Wollaston Donation from the Geological Society.

BENJAMIN NEVE PEACH,

F.R.S.E., F.G.S. District Surveyor of the Geological Survey of Scotland. Past President of the Physical Society of Edinburgh. Recipient of the Wollaston Donation Fund of the Geological Society in 1887. For thirty years actively engaged on the Geological Survey, during which time he has mapped many of the most complicated districts of Scotland. Has charge of the surveying of the North-West Highlands, and has taken the leading part in unravelling the remarkable structural complications of that region. Author of various papers on palæontological subjects:—"On some New Crustaceans from the Lower Carboniferous Rocks of Eskdale and Liddesdale" (Trans. Roy. Soc. Edin., vol. xxx., p. 73); "On some new species of Fossil Scorpions from the Carboniferous Rocks of Scotland" (*ibid.*, p. 399); "Further Researches among the Crustacea and Arachnida of the Carboniferous Rocks of the Scottish Border" (*ibid.*, p. 511); "On some Fossil Myriapods from the Lower Old Red Sandstone of Forfarshire" (Proc. Roy. Phys. Soc. Edin., vol. vii. p. 179). Joint author with Mr. J. Horne of many papers on stratigraphical and physical geology, including:—"The Glaciation of the Shetland Isles" (Quart. Journ. Geol. Soc., vol. xxxv. p. 778); "The Glaciation of the Orkney Islands" (*ibid.*, vol. xxxvi. p. 648); "The Old Red Sandstone of Shetland" (Proc. Roy. Phys. Soc. Edin., vol. v. p. 30); "The Glaciation of Caithness" (*ibid.*, vol. vi. p. 316); "Report on the Geology of the North-West of Sutherland" (NATURE, vol. xxxi. p. 31); "The Old Red Sandstone Volcanic Rocks of Shetland" (Trans. Roy. Soc. Edin., vol. xxxii. p. 539); "Report on the Recent Work of the Geological Survey in the North-West Highlands of Scotland, based on the Field Maps of B. N. Peach, J. Horne, W. Gunn, C. T. Clough, L. Hinxman, and H. M. Cadell" (Quart. Journ. Geol. Soc., vol. xliv. p. 378).

ALEXANDER PEDLER,

F.C.S., F.I.C., Fellow of the University of Calcutta; Professor of Chemistry, Presidency College, Calcutta; Meteorological Reporter to the Government of Bengal; and Curator of the Bengal Government Museum at Calcutta. Author of papers on "An Isomeric Modification of Valeric Acid," "Calcutta Coal Gas," "The Use of the Radiometer as a Photometer," "Cobra Poison," "The Past and Present Water Supplies of Calcutta," "Technical Education for Bengal," "The Faln Point Cyclone of September 22, 1885," published in the Proc. Roy. Soc., the Journ. Chem. Soc., the Journ. Asiat. Soc. Beng., and elsewhere.

AUGUSTUS D. WALLER, M.D.,

Lecturer on Physiology at St. Mary's Hospital Medical School. Distinguished as a Physiologist. Lauréat de l'Institut de France (Prix de Physiologie Expérimentale). Contributions to the Royal Society:—"On the Influence of the Galvanic Current on the Excitability of the Motor Nerves of Man" (with Dr. de Watteville, Phil. Trans., 1882); "On the Influence of the Galvanic Current on the Excitability of the Sensory Nerves of Man" (Roy. Soc. Proc., 1882); "On the Action of the Excised Mammalian Heart" (with Dr. Reid, Phil. Trans., 1887); "On the Electromotive Changes connected with the Beat of the Mammalian Heart" (Phil. Trans., 1889). Contributions to the *Journal of Physiology*:—"On the Rate of Propagation of the Arterial Pulse Wave" (vol. iii., 1880); "A Demonstration in Man of Electromotive Changes accompanying the Heart's Beat" (vol. viii., 1887) Contributions to other journals, English and foreign:—"Die Spannungen in den Vorhöfen des Herzens" (*Arch. f. Anat. u. Physiol.*, 1878); "On Muscular Spasms known as Tendon Reflex" (*Brain*, 1880); "Nouvelles Expériences sur les Phénomènes nommés Réflexes tendineux" (with Dr. Prévost, *Rev. Méd. de la Suisse Romande*, 1881); "Sur la Contraction de l'Ouverture" (*Journ. de Physiol.*, 1882), &c.

NOTES.

THE Council of the British Association for the Advancement of Science have nominated Dr. J. S. Burdon Sanderson, F.R.S., Waynflete Professor of Physiology in the University of Oxford, President for the meeting of the Association which will be held next year at Nottingham. Dr. Sanderson has accepted the nomination.

THE Gold Medal of the Linnean Society has this year been awarded by the Council to Dr. Alfred Russel Wallace for his important contributions to the literature of zoology. The medal will be presented at the forthcoming anniversary meeting of the Linnean Society, to be held at Burlington House on the 24th inst.

WE regret to have to record the death of the illustrious chemist, August Wilhelm Hofmann. He died on May 5. Prof. Hofmann was well known in England, where he spent many of his best years. On Liebig's recommendation he was appointed in 1848 Superintendent of the Royal College of Chemistry, in London. This institution, which made great progress under his care, was in 1853 merged in the Royal School of Mines as the Chemical Section. He became a Warden of the Royal Mint in 1855. In 1864 he accepted the chair of chemistry at Bonn, and in the following year he was called to Berlin, where he spent the rest of his life as Professor of Chemistry. He made many contributions to the *Annalen der Chemie*, to the Transactions of the Chemical Society, and to the Philosophical Transactions of the Royal Society, of which latter institution he was made a Fellow in 1851, in recognition of his services to science. In 1854 he was awarded a Royal Medal for his "Memoirs on the Molecular Constitution of the Organic Bases." Some of his discoveries led to industrial results of the highest importance. The high respect in which Prof. Hofmann was held in Germany was shown at his funeral, which took place on Monday. It was very largely attended, and, according to the Berlin correspondent of the *Standard*, "was in all respects worthy of a prince of science." The correspondent says:—"The Empress Frederick, immediately on receiving the news of the Professor's death, telegraphed to his widow, 'My deepest sympathy in your great, your irreparable loss. I am deeply shocked by the quite unexpected news of your dear husband's death.' Her Imperial Majesty sent a splendid laurel wreath bearing her initials, to be placed on the coffin, and a Court Chamberlain represented Her Majesty at the funeral. The Minister of Education and numerous officials of his Department, all the members of the Berlin Academy, and almost all the professors and students of the University, accompanied the funeral procession to the cemetery."

We regret also to have to announce the death of Dr. James Thomson, F.R.S., Emeritus Professor of Civil Engineering in the University of Glasgow, Lord Kelvin's brother. Dr. Thomson died on Sunday last. He was seventy years of age.

There are vacancies for zoological students at the Cambridge University's tables in the Zoological Station at Naples, and in the Marine Biological Society's Laboratory at Plymouth. Applications are to be sent to Prof. Newton, Chairman of the Special Board for Biology and Geology, by May 30.

General Isaac T. Wister, President of the Philadelphia Academy of Sciences, has placed in the hands of trustees for the benefit of the University of Pennsylvania, 100,000 dollars for the erection of a Museum with laboratories, to contain the Wister and Horner Museum of Human and Comparative Anatomy. He has also given an endowment of 3000 dollars a year for the maintenance of a curator, whose occupation shall consist largely of original research.

We referred lately to the interesting Horticultural Exhibition for which preparations were being made at Earl's Court. The Exhibition was formally opened on Saturday last by the Duke of Connaught, and promises to be a great success.

A German scientific expedition under Dr. Erich von Drygalski started from Copenhagen for West Greenland on May 1. Dr. von Drygalski is accompanied by Dr. H. Stade, the meteorologist, and Dr. E. Vanhöffen, the zoologist. They were to make in the first instance for Umanak Fjord. They do not intend to return until the autumn of 1893.

We are glad to welcome a third edition of Clerk Maxwell's great "Treatise on Electricity and Magnetism" (Clarendon Press). The task of seeing the proofs through the press could not be undertaken by Mr. W. D. Niven, who had charge of the second edition; so the duty has been fulfilled by Prof. J. J. Thomson, who, we need scarcely say, has done his work admirably. Twenty years have passed since the work was written, and during that time the sciences of electricity and magnetism—thanks in part to the influence exerted by this treatise—have made rapid progress. Prof. Thomson explains that when he began to prepare the present edition he intended to give in foot-notes some account of the advances made since the publication of the first edition, not only because he thought it might be of service to students, but because all recent investigations have tended to confirm in the most remarkable way Maxwell's views. He soon found, however, that if this intention were carried out the book would be disfigured by a disproportionate quantity of foot-notes. His notes have accordingly been thrown into a slightly more consecutive form, and will be published separately. A few foot-notes relating to isolated points which could be dealt with briefly are given. Prof. Thomson has added something in explanation of the argument in those passages in which he has found from his experience as a teacher that nearly all students find considerable difficulties. He has also attempted to verify the results which Maxwell gives without proof. He has not in all instances succeeded in arriving at Maxwell's results, and in such cases he has indicated the difference in a foot-note. Maxwell's method of determining the self-induction of a coil is reprinted from his paper on the dynamical theory of the electro-magnetic field.

At the time of our last issue, an anticyclone lay over the whole of the British Islands and part of the Atlantic, with north and north-east winds of some force, under the influence of a depression existing over North Germany. Daily temperatures were, generally, considerably below the normal values; slight snow fell on the south coast on the morning of the 6th, and the grass thermometer fell as low as 18° on that night in London. The anticyclone afterwards moved southwards, while a depression, which had set in at the northern stations, spread towards the North Sea, the winds shifted to west and north-west, and temperatures gradually increased; the maxima exceeded 60° over the inland parts of England on Sunday, and even reached 70° at several stations on Monday, with fine weather generally. The amount of rainfall is considerably below the average. The Weekly Weather Report for Saturday last shows that the deficiency, since January 3, amounts to 7·7 inches in the west of Scotland and to 5·3 inches in the south-west of England. During the last few days this country has again been under the influence of an anticyclone, with fine, warm weather generally.

The Pilot Chart of the North Atlantic Ocean, in its review of weather during April, says that the storms on the Atlantic, like those of the preceding month, were confined almost entirely to the American coast and the western part of the ocean, and they again followed somewhat abnormal northerly tracks. Two of the most severe storms whose tracks are plotted on the chart, occurred during the last few days of March. During the first week of April, pleasant anticyclonic weather prevailed along the American coast south of Hatteras, but two severe storms moved eastward over Labrador on the 3rd and 6th respectively, the first of which was followed by a storm of slight energy that formed south of Cape Race on the 4th, and the second by one that reached Hatteras from inland the morning of the 8th, but neither of these, nor those of the 9th to 11th, and 15th to 16th, along the Nova Scotia coast, were at all severe. The only remaining storms of any noteworthy severity, so far as indicated by data received at the office of the Pilot Chart up to date of publication, were those that originated between the Grand Banks and Bermuda on the 13th and 18th respectively. The track of a depression of considerable energy is indicated near the Azores on the 6th, 7th, and 8th, and another, but of slight energy only, in the English Channel on the 15th and 16th. The persistent anticyclonic weather over the British Isles and Central Europe during the last week of March and the first half of April, may be said to have turned to the northward the storms that formed over the ocean, and it seems probable that the persistent northerly winds thus caused off Labrador and Newfoundland helped along the ice that is now working its way southward off the Grand Banks. Fog has been reported in increasing quantities, also, and it will continue to increase until midsummer.

We note the publication of two new monthly meteorological bulletins for Russia, which are issued nearly closely up to date, viz. by Prof. A. Klossovski, Odessa, with Russian and German next, and by Prof. P. Brounof, Kieff, in Russian, with a few notes in French. Both bulletins contain observations taken three times daily, with daily and monthly means, while the Odessa publication contains monthly rainfall values, and maximum and minimum temperatures for about a hundred stations in South-West Russia. The Kieff observations are preceded by some remarks (in Russian only) on the temperature and density of snow at various depths.

A REMARKABLE aurora borealis was seen at Moscow during the night of April 26–27. It began at 11.50 p.m. with a dark segment fringed by a bright border, the summit of which stood a few degrees to the west of the meridian. Bright rays were projected to the constellations of Auriga, Perseus, and Cassiopœia, while the longest rays reached the Pole star. It attained its maximum at 11.56, but four minutes later it began to die away, no traces of it being seen at 12.15 a.m. At 2 a.m. three beams of light appeared again for a few seconds. It is worthy of note that on April 26 a large accumulation of sun-spots was observed at Moscow; it consisted of ten groups of spots. It may also be added that another aurora borealis, much brighter than the above, was seen at Moscow on March 12, at 4 a.m. It lasted for nearly half an hour.

ALL who have occasion to use the magic lantern will be interested in the fact that a lantern may now be seen at the Crystal Palace finely illuminated by the arc-light. This instrument was designed by Mr. T. C. Hepworth, F.C.S., who uses it to illustrate lecture entertainments in connection with the Crystal Palace Electrical Exhibition. The lamp employed is the Brockie-Pell, which has been modified by Messrs. Newton to make it more suitable for the particular work required. It gives a pure white light, and its brilliance is said to be several times that of the lime-light. The electric arc-light has before been applied to lantern projection, but it is claimed that the Crystal Palace lantern is on quite an unprecedented scale.

M. MESDRAN, of Paris, sends us a prospectus, in which he sets forth the merits of a machine he has invented for the proper boiling of eggs. Hitherto, it seems, mankind have boiled eggs on a wholly false principle. M. Mesdran claims that he has solved the problem, and that his invention is nothing short of "a revelation both from the hygienic and the gastronomic point of view." The invention has been patented in England.

AN interesting trace of Palæolithic man has lately been discovered in Hermann's Cave in the Harz. Excavations were being carried on in the cave, under the superintendence of Herr Grabowsky, when a flint which had all the appearance of having been fashioned into the form of a knife was found among the remains of reindeer and other glacial or Arctic animals. The object could not have been brought into the cave by non-human means, as flint is not found anywhere in the neighbourhood. A paragraph on the subject appears in the current number of *Globus*, the editor of which appends a note to the effect that the flint (which lay before him as he wrote) has undoubtedly been artificially worked into its present shape.

DR. DANIEL G. BRINTON has issued an interesting pamphlet, in which he urges the claims of anthropology as a branch of University education. He gives an account of the aims and methods of the science, and then sketches a general scheme of anthropological instruction. Dr. Brinton would begin with lectures on somatology, including internal somatology, external somatology, psychology, and developmental and comparative somatology. Then would come ethnology, in connection with which he would deal with sociology, technology, religion, linguistics, and folk-lore. Under ethnography he would discuss the origin and subdivisions of races; and archæology he would divide into "general" and "special." Laboratory work would include (in the physical laboratory) such tasks as the comparing and identifying of bones, the measuring of skulls, &c.; and (in the technological laboratory) the study of stone and metal implements, textile materials, &c. There would also be library work and field work. Students who might wish to obtain an adequate notion of the science would have to attend a course of thirty or forty lectures, and give twice as many hours to laboratory work. That would be the minimum amount of study. Those who might desire to instruct others, or to prepare for independent research, would devote to the science the greater part of their time during two or three years.

THE structure of the cells of Bacteria continues to occupy the attention of biologists, and a communication on the subject to the St. Petersburg Society of Naturalists (*Memoirs*, vol. xxi., Botany), by W. K. Wahrlich, is worthy of notice. Careful study of several species of Bacteria has led the author to the conclusion that only two substances are to be detected in the cell—chromatin, and linin, which surrounds the former. The leading part in the formation of spores belongs to chromatin, which is used entirely for this purpose, while the linin substance is used for the formation of the exosporium. As to the involutional forms, the author can only confirm the opinions of De Bary, Nägeli, and Büchner as to their being representative of a pathological state, or of a degeneration of the cell; chromatin disappears in such cells, and two or three vacuoles appear in their linin part. The bacterial cells thus appear to be simple nuclei, surrounded by membranes, but devoid of cytoplasm; chromatin is their most important part, and when it disappears the cell can no longer reproduce itself or continue an independent life.

A REPORT was lately spread in the United States to the effect that the Government intended to introduce the mongoose in the West to exterminate the rodents which annoy farmers there. The editors of the *Naturalist* wrote to the Department of Agriculture for information on the subject, and received in reply a letter to the effect that no such "rash act" had ever been contemplated, the introduction of exotic species being contrary to the Department's policy. The *Naturalist* expresses cordial approval of this answer, evil having, it maintains, "invariably resulted from the introduction of exotic animals into countries when no adequate natural restriction to their increase exists."

MR. F. W. WARD was commissioned last year by the Hon. Sydney Smith, then Minister of Agriculture in New South Wales, to report upon the relations of fruit production in that colony to the English market. The report was presented some time ago, and is printed in the February number of the *Agricultural Gazette of New South Wales*. Mr. Ward is convinced that London offers an attractive market for the fruit products of Australasia in their green, dried, and canned forms. All testimony, and most emphatically that of the European growers, is, he says, to the effect that London is, and always will be, the great fruit market of the world. There is also, he adds, a consensus of opinion to the effect that Australasia will gain the largest share of the advantage in regard to this market, consequent upon the reversal of the seasons. Other territories in the southern hemisphere will dispute the market with Australasia; but Mr. Ward anticipates that the energy and intelligence of Anglo-Saxon communities, operating upon good and cheap soil, an unsurpassed, if not an unrivalled, climate for fruit production, and splendid facilities of over-sea carriage, will fully or more than compensate for the one great disadvantage of geographical distance. The London market for Australasian fruit resolves itself, for the most part, into a question of carriage. What needs to be done is to minimize the cost of conveying green fruit from (say) Sydney to London, and to solve the chemical problems attaching to the attempt to utilize the cool chambers of swift steam-ships in such a way as to preserve the appearance and flavour of so perishable a commodity as fruit through the unavoidable space of time and varying latitudes of the journey. Mr. Ward is of opinion that there are sound reasons for expecting that "these problems will be solved and that the market will be captured."

The Echinoderm fauna of Kingston Harbour, Jamaica, seems to be remarkably numerous and varied. Mr. George W. Field, who has been investigating it, contributes some notes on the subject to the April number of the "Johns Hopkins University Circulars." About twenty-eight species of Echinoderms were found in Kingston Harbour and about the cays at its mouth, and a longer residence and dredging in the deeper waters would probably, Mr. Field thinks, have increased the number considerably. The difficulties of dredging were very considerable, arising in part from the nature of the bottom, from the unmanageableness of the boat, and chiefly from the wind. There always seemed to be a perfect calm or a gale; the calm periods between exceedingly short. However, considerable dredging was done by various members of his party. The surface tow-net showed a wonderful richness of the larval Echinoderms in the pelagic fauna, chiefly however, during their stay, confined to Ophiurid, Echinid, and Spatangid plutei, the relative abundance being in the order named. During the month of June they were abundant, and in early July they were extremely numerous. They were found in greatest numbers in tows made about sunrise. In the evening towing they were invariably absent. These larvæ, says Mr. Field, appear to come to and remain at the surface from midnight until about sunrise; after that to gradually disappear until three hours after sunrise, when they are rarely found at the surface. Their appearance seemed to be little or not at all influenced by the tide, but did depend very much upon the quantity of flood water poured into the harbour by the various rivers. In its general aspect the Echinoderm fauna shows no very considerable variation from that of the Bahamas and Southern Florida, though apparently richer in species and in individuals.

According to an official report published in the *Deutsches Kolanialblatt* for April, the Germans have every reason to be satisfied with the way in which the resources of Cameroon are being developed. The industry and trade of the colony are said to be in a flourishing condition. The chief products are palm oil and palm kernels. There are many elephants in the territory, and ivory is still exported. Caoutchouc is also obtained in considerable quantities, and ebony fetches good prices. In 1891 there were in Cameroon 166 Europeans, of whom 10 were women. There were 109 Germans and 31 Englishmen. The exact number of natives is not yet known, but it is calculated that there are 20,000 Dualla on the Cameroon river, 25,000 Bakwiri in the Cameroon Highlands, and 20,000 Bamboko towards the west of the hilly district.

A valuable paper presenting a revision of the American species of Rumex occurring north of Mexico, by William Trelease, appears in the third annual report of the Missouri Botanical Gardens, and has also been issued separately. Rumex is a genus which has been held to include from 100 to about 130 species, the greater part of which belong to the north temperate region of both continents. "Of the twenty-one species," says Mr. Trelease, "recognized by me as occurring within our flora, eleven were characterized and named by Linnæus in the first edition of the 'Species Plantarum,' and only five have been named by American botanists." The biological interest of the genus arises chiefly, as he points out, from the protective acidity of the sorrels and some docks, and the occurrence of tannin and a bitter principle in others; their protandry and exclusive adaptation to wind pollination; and the adaptation of the greater number of species to wind dissemination, by the enlargement of the inner segments of the perianth during ripening, although some of those with fimbriate valves may profit by attachment to animals.

In the latest instalment of the Proceedings of the Academy of Natural Sciences, Philadelphia, Messrs. H. Skinner and L. W. Mengel give an account of some of the insects taken by the expedition which the Academy sent to Greenland in 1891. The insects captured were divided among the different orders as follows:—Hymenoptera 25 specimens, Coleoptera 4 specimens, Lepidoptera Rhopalocera 143 specimens, and Heterocera 143. They were captured by Mr. L. W. Mengel, entomologist to the expedition, and Dr. W. E. Hughes, ornithologist. The specimens are all from the West Coast, and were taken at three principal localities, McCormick Bay, Herbert Island, and Disco.

Acetyl fluoride, CH_3COF, has been prepared by M. Maurice Meslans, and is described by him in the current number of the *Comptes rendus*. As was to be expected, it is a substance considerably more volatile than acetyl chloride. Its boiling-point is 19°·5, very near that of hydrofluoric acid itself, and hence upon a warm day it takes the form of a gas, while at temperatures below 19°·5 it assumes the liquid state. It has been prepared by M. Meslans by causing various inorganic fluorides to react upon acetyl chloride. Thus when silver fluoride and acetyl chloride are heated together in a sealed tube to 260°, a small quantity of acetyl fluoride is formed. The acetyl chloride, however, is much more completely converted to fluoride when it is passed in the state of vapour through a long silver tube filled with dry silver fluoride and heated to 300°. Upon allowing the issuing vapour to pass into a strongly cooled receiver, acetyl fluoride condenses in the liquid form. Another mode of preparation consists in allowing arsenic fluoride to fall drop by drop upon acetyl chloride contained in a copper vessel, when energetic action at once occurs in the cold. The exit tube is attached to a spiral of leaden tubing, arranged as an inverted condenser, in order to retain either of the liquid reacting substances, and the last traces of acetyl chloride are removed by subsequently allowing the escaping vapour to pass through a copper U-tube filled with fragments of silver fluoride and heated in a bath of nitrates to 300°. The acetyl fluoride may then be condensed in a strongly cooled receiver. Instead of arsenic fluoride the solid trifluoride of antimony may be employed, and the operation performed in a glass flask, an ordinary inverted glass condenser being used to retain any escaping acetyl chloride. By far the most advantageous mode of preparation, however, consists in reacting with acetyl chloride upon zinc fluoride. One hundred grams of zinc fluoride are introduced in successive portions of ten grams each into a strong glass flask cooled by a freezing mixture and containing a hundred and fifty grams of acetyl chloride. The flask is then sealed, warmed to 40°, and again cooled. It is subsequently opened, while surrounded by the freezing mixture, and placed in connection with a leaden worm whose extremity passes down into a second flask surrounded by ice and containing a little dry zinc fluoride. The acetyl fluoride is then distilled over into the second flask, and upon redistillation over the zinc fluoride contained in the flask it is obtained in an almost pure condition. The liquid may be preserved unchanged in a dry glass vessel, but if moisture obtains access the glass is rapidly attacked. If the vessel containing the liquid is placed in connection with a tube standing over mercury, and the liquid warmed by holding the vessel in the hand, the new fluoride may be collected in the gaseous state, and preserved as a gas, provided the temperature of the room is superior to 19°·5. Both the liquid and the gas are colourless.

They burn with a blue flame upon ignition, producing water vapour, carbon dioxide, and hydrofluoric acid. They possess an odour somewhat resembling that of carbonyl chloride. Water dissolves about twenty times its volume of the gas, but the liquid does not mix with water, a very small proportion only being dissolved, and suffering slow decomposition. Alcohol, ether, benzene, and chloroform dissolve it in all proportions.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. C. Drew; a Grivet Monkey (*Cercopithecus griseo-viridis* ♀) from North-east Africa, presented by Mr. George Conquest; a Grey Ichneumon (*Herpestes griseus*), from India, presented by Mr. J. E. Barber; a Common Fox (*Canis vulpes* ♀), British, presented by Miss Nora Dunn; a Song Thrush (*Turdus musicus*), British, presented by Mr. Baldwin M. Smith; an Alexandrine Parakeet (*Palæornis alexandri* ♂) from India, presented by Mr. E. Bond; two Cerastes Vipers (*Vipera cerastes*) from Egypt, presented by Colonel Holled Smith; a —— Lizard (*Amphibolurus* sp. inc., from Australia, presented by Mr. Herbert E. Swayne; a Guinea Baboon (*Cynocephalus sphinx* ♀) from West Africa, a Rhesus Monkey (*Macacus rhesus* ♂), a Grey Ichneumon (*Herpestes griseus*) from India, two Punctated Agoutis (*Dasyprocta punctata*), a King Vulture (*Gypagus papa*) from Central America, a White-eyebrowed Guan (*Penelope superciliaris*) from South-east Brazil, deposited; a White-faced Heron (*Ardea novæ-hollandiæ*) from Australia, eight Ruffs (*Machetes pugnax* 4 ♂ 4 ♀), British, purchased; a Reindeer (*Rangifer tarandus* ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

PHOTOGRAPHIC AND VISUAL MAGNITUDES OF STARS.—At the Amsterdam Academy of Sciences on April 2, Prof. J. C. Kapteyn communicated the results of an investigation on the systematic differences between the photographic and visual magnitudes of stars in different regions of the sky. The comparison of the photographic diameters of stars of equal visual magnitude (according to Gould and Schonfeld's estimations) on 370 plates of the southern sky, shows that the actinic effect of stars in or near the Milky Way is much greater than that of stars in high galactic latitudes. Prof. Kapteyn has examined the different causes which lead to this variation. There is, first of all, the influence of different meteorological conditions; next, systematic errors in the catalogue of visual magnitudes used for comparison; and thirdly, peculiarities in the light of the stars. The discussion leads to the conclusion that the difference of magnitude is not appreciably affected by the first of these causes. And since, taking everything into consideration, the errors of estimated visual magnitudes could not possibly exceed 0·3 magnitude, there is no doubt that the difference of half a magnitude or more, indicated by the photographs, is due to the quality of light emitted. It is said that Prof. Pickering's idea that the Milky Way ought to be considered as an aggregation of stars of the first type is only sufficient to account for a difference of about 0·1 magnitude. Thus it appears that the light of stars in or near the Milky Way, like those of Group IV., is richer in violet rays than that of other stars.

PHOTOGRAPHS OF THE LYRA RING NEBULA.—In addition to the work on the Carte du Ciel, Prof. Denza, of the Vatican Observatory, has taken up the photography of nebulæ. Beginning with the Ring Nebula in Lyra, he has made five exposures on this object, from half an hour up to nearly two hours' duration. To bring out the fine detail, development has been carried on for about twenty minutes in each case. The negative which had received the longest exposure was presented to the Paris Academy on April 25. Viewed microscopically, the star at the centre of the nebula is seen to be joined to a smaller one near the nebulosity, and each of them can be broken up into other more or less brilliant points. A large number of condensed regions are well visible in the nebula. The location of these leads Prof. Denza to agree with Secchi that "L'anneau se prolonge dans le sens du plus grand axe, et que les parties les plus denses sont dans la direction du petit axe."

DETERMINATION OF THE CONSTANT OF ABERRATION.—Prof. G. C. Comstock contributes the provisional results of a determination of the constant of aberration to the *Astronomical Journal*, No. 261. The method adopted in the investigation is a modified form of that used by M. Lœwy, three reflecting surfaces being placed in front of the objective of the telescope instead of two. Images of stars in different portions of the heavens are thus simultaneously produced in the focal plane of the objective, and a micrometer is used to measure the distance between those of two given stars, when each pair of surfaces is successively employed. Then, if d represent the distance between the images of two stars as measured with the micrometer, Δ the angle subtended at the earth by the stars, R the effect of refraction in changing the true Δ into an apparent Δ', and K a correction depending upon the squares of the errors of adjustment of the mirrors, we have—

$$\Delta = 120^\circ + K + d + R.$$

The provisional value of the aberration constant derived from Prof. Comstock's observations is—

$$20''{\cdot}494 \pm 0''{\cdot}017.$$

An investigation of the refraction has also been made, resulting in the detection of a real variation. The refraction is at a maximum near the time of the winter solstice and a minimum near the summer solstice, but the exact epoch and amplitude have not yet been determined.

STAR MAGNITUDES.—"The Estimation of Star Magnitudes by Extinction with the Wedge," was the subject of an interesting paper by Captain Abney before the Royal Astronomical Society, many of the experiments from which his conclusions were drawn being made from a paper which he and General Festing communicated to the Royal Society on colour photometry. In the experiment for determining the amount by which the intensity of any ray of the spectrum would have to be reduced before it became invisible, the absolute intensity of the D line was fixed upon for the basis, from which all the other intensities could be directly calculated. With the arrangement he described, the D line was reduced to the 350 ten-millionths part of a standard amyl lamp, while under the same conditions the green light E had to be reduced to 65, F to 150, G to 3000, and the red to 110,000 ten-millionth part. By making the rays equal to one amyl lamp the numbers obtained were for D 350, E 35, F 17, G 15, and for C 22,000 ten-millionths part.

These numbers showed that to produce extinction for two lights of equal luminosity, say of colours C and G respectively, the latter was nearly 1500 times greater than that required for the other. He then referred to the extreme persistency of the violet sensations, they being 1500 times more persistent than the red and about 25 times more than the green, pointing out that the violet sensation would be the last to be extinguished. The function of the wedge, then, was not to obliterate the spectrum but to eliminate the violet sensation contained in its light. By determining star magnitudes by this method of extinction, the results obtained, he says, "should agree better with those obtained by photography than those obtained by eye estimation," the first being obtained by estimation of the E light, the second of the light between G and F, and the third from that near D.

Referring to colour extinction he mentions that although most of the faint stars are known to be of a bluish colour it does not follow that "they are not red." The blue tint is brought about by the faintness of the light, which makes all colours appear grey, and "as the violet sensation disappears last, it frequently happens that you get the red and green sensations as grey, and the violet just above the colour limit, thus giving a grey blue." He suggests that with telescopes of large aperture these stars might be seen in colours.

THE INSTITUTION OF MECHANICAL ENGINEERS.

AN ordinary general meeting of the Institution of Mechanical Engineers was held on the evenings of Thursday and Friday of last week. There were two items of exceptional interest on the programme, the first being the inaugural address of the new President, Dr. William Anderson, F.R.S.; and the second the report of the Committee appointed by the Institution to make trials on marine engines. The President in his address gave a brief review of the progress of the Institution since its foundation in 1847. For the first thirty years of its existence the Institution was a provincial Society, having its head-quarters in Birmingham. In 1877 it was determined to remove to London, as it was thought that the wealth and influence that had been acquired was sufficient to give a position of national importance which could hardly be held by a Society having its head-quarters in any other city than the metropolis. There was naturally a strong opposition to the migration, but the change was made, and since then the importance of the Institution has gone on steadily increasing, until at the present day it is second only to the Institution of Civil Engineers. The Institution was started in 1847 with 107 members, the annual income being £515. During the first thirty years the membership increased about tenfold, but at the end of the fourteen years that the head-quarters have been in London it has increased to twenty-fold; that is to say, in 1877, when the migration was made, the numbers were about one thousand, whilst last year they were over two thousand—actually 2077. The annual income was last year £7212, and the accumulated investments of the Institution are now £22,536.

A somewhat acrimonious correspondence has been published lately in the pages of a weekly journal, and the President, somewhat unnecessarily perhaps, thought fit to reply to this. A complaint had been made that the papers were few and poor. Dr. Anderson referred to the large number of scientific Societies now existing, and the difficulty of providing good papers. "We have been spoiled and cloyed," he says, "by the rapid progress of mechanical engineering; so that papers which are not revelations of something new are condemned as unworthy of the Institution. Is there any form of steam-engine, for example, which it would be worth while now to describe, unless it be some monster of exceptional proportions, the details of which we should like to see in our Transactions? Who would like to read a paper on a bridge of even 800 feet span, and to illustrate it with all the type and plates which characterized the two accounts of the Britannia Bridge, when the Forth Bridge, a structure of more than double that opening, has recently become familiar to us? I am afraid that, in consequence of the state at which we have arrived, and, in respect of originality, the untoward age in which we live, we must be content with many papers that may justly be termed poor so far as novelty alone is concerned. We must, therefore, rely for excellence on a more scientific treatment of our subjects, and on the care with which the details of construction are worked out and presented in the illustrative drawings. Our critics should remember also that originality is not our only quest—that we are not all veterans to whom design comes almost by instinct: we have a large body of younger and less experienced members, and to them I feel sure, from my past experience, that our proceedings offer practical examples and guidance which are appreciated all over the world, and the desire to possess which is, I take it, the main cause of the ever-increasing strength of the Institution."

The President next referred to the work done by the different Research Committees of the Institution which have been engaged for some years past in investigating engineering subjects upon which information appeared most desirable. There have been Committees on riveting, on friction, on steam-jacketing engine cylinders, and other matters, including marine-engine trials, the last report of the Committee on the latter subject having been presented at the meeting now under notice. It would be difficult to imagine a more useful and legitimate purpose upon which the funds of the Institution could be spent. The work that is over and over again done, generally in a partial and imperfect manner, by private firms, in getting information on many points of engineering practice, represents a sad loss of time and money. The work of the Research Committees of the Institution should put an end to a great deal of this, and will so help the advance of engineering practice, to the benefit not only of engineers, but of the whole civilized world. The President made another suggestion which would tend to the same end, and which it is hoped may be carried out. "There is," he said, "another sphere of usefulness in which our abundant means would enable us to do good service; it is in the compilation of a brief reference index to all mechanical matters at home and abroad. Were we to establish a staff—and it might be a very modest one—whose duty it would be to index under proper heads every important article relating to mechanical science which comes out week by week, we should in time, and at moderate cost, form an invaluable record, from which an inquirer would be able to find in a few minutes where to look for complete information on any subject connected with our special branch of engineering." The Royal Society is doing a similar work for scientific papers generally; and in the United States Messrs. Haferkorn and Heise have compiled a most useful index of books printed in English relating to technical matters, but the work stops at 1888, and does not contain references to the isolated letters and papers which appear in English and foreign journals.

Dr. Anderson, as every one knows, holds the important post of Director-General of Ordnance Factories, and it was natural he should make some reference to the various establishments—the chief of which, of course, is Woolwich Arsenal—under his control. Here, again, public criticism has been exercised of late, not altogether favourably, and a good part of the address was taken up with an apology for Woolwich. Taking the side of the case selected by Dr. Anderson for discussion, there is no doubt he made out a very good case. It is perfectly impossible that all inventions should be adopted, and therefore it is evident the authorities with whom these matters rest must reckon with a great many hostile critics. The address gave some interesting details of the way in which the Ordnance departments are managed, but into this question we need not now enter. The difficulty of finding subjects for papers which were altogether novel had been previously referred to in the address; but, notwithstanding that there is little scope for originality, Dr. Anderson pointed out that some problems still remain to be solved. Among them is one which is of the greatest practical importance to mechanical engineers, while at the same time it is of extraordinary theoretical interest. This was the question of the nature and composition of steel, and alloys generally. Since the year 1879 the Institution had been engaged in trying to unravel the mystery which surrounds the behaviour of steel in connection with its chemical and molecular composition, combined with changes of temperature. The researches of Sir Frederick Abel, Dr. Sorby, Mr. Osmond, Mr. Hadfield, and Prof. Roberts-Austen, aided by the Le Chatelier pyrometer, have given the inquiry new life. Dr. Anderson expressed great hope that the active measures taken by the Institution, through the Alloys Research Committee, would result, at no distant time, in the solution of the enigma, and in the establishment of definite laws. The problem, however, is excessively involved. It amounts, in fact, to a consideration of the number of permutations or combinations possible among some ten variables, the relations of which to each other are also dependent, not only on actual temperature, but also on the rate of its changes, and on the uniformity of these changes, throughout the mass. The address next made reference to the fact that pure iron is allotropic, and exists in both the hard and soft state. Carbon also exists in two forms in steel, either combined or suspended in the mass; and there are other ingredients necessary to take into account. In consequence of changes due to temperature also, the chemist is impotent to pronounce from mere analysis what the quality of steel may be. On the other hand, the ordinary mechanical tests are not of much avail, because the specimens are not and cannot be in the same condition of internal stress—on which again the molecular arrangement appears to depend—as the masses from which they are cut. Moreover, specimens for mechanical testing cannot always be taken from the central parts of the huge forgings and castings now in use for many purposes. Under these circumstances Dr. Anderson considered that the method of noting the rate of cooling by curves automatically traced—as now so ingeniously worked out by Roberts-Austen—affords the best promise of placing in the hands of the mechanic a means of judging at any rate of the uniformity in composition of the material, and even perhaps of its actual chemical nature, so far as this affects his wants. As additional advantages the thermo-electric autographic apparatus is cheap; it occupies but little space, it can be employed in an ordinary room, and the results sought can be obtained in a few minutes.

The use of petroleum or mineral oil next occupied a place in the address, the author being of opinion that as a source of power it would rapidly gain ground. In 1888, Priestman Bros. brought out their engine, working with a heavy oil having a high flashing temperature. That engine was tested by the present Lord Kelvin (then Sir William Thomson) and the author independently, and gave an efficiency of one brake horse-power to 1·73 lb. of oil. At the next year's show the consumption fell to 1·42 lb.; in 1890, to 1·243 lb., and Prof. Unwin this year reports that a brake horse-power has been obtained by the combustion of 0·946 lb. Much yet remains to be done. The useful work on the brake is under 14 per cent. of the energy latent in the fuel, while the heat carried off by the water jacket round the cylinder, and by the exhaust is equivalent to 75 per cent. of the total thermal capacity of the fuel. Dr. Anderson was of opinion that a combination of the direct combustion engine with the spirit-engine of the Yarrow type would give the best results, especially if a more advantageous cycle than that of the Otto gas-engine can be adopted.

The address next proceeded to deal with the question of the capacity of the earth to supply the ever-increasing demand for petroleum, and to enquire whether it would be possible to substitute it largely for coal as a source of heat, owing to the fact that we should have to go deeper and deeper in the future to reach workable coal measures. In connection with this problem the address gave particulars of the researches of Mendeleeff, and described his theory of the continuous formation of petroleum by the action of water on the molten rocks in the interior of the earth. The speculation is one of great interest, but has already been dealt with in these pages.

The vote of thanks to the President for his address was moved by Sir Frederick Bramwell and carried with acclamation.

After the reading of the address the Report of the Marine Engine Trials Research Committee, which had been prepared by the Chairman of the Committee, Prof. Alexander B. W. Kennedy, was read. This report dealt with the trials of the Belgian channel steamer *Ville de Douvres*, which had been generously placed at the disposal of the Committee by the Belgian Government. This vessel is one of the line which carries the mails between Ostend and Dover, and was built and engined by the Société Cockerill, of Seraing, Belgium, and is a comparatively new vessel, having been delivered in the year 1890. The propelling machinery consists of a pair of compound surface-condensing paddle engines. Vessels of this class are mainly designed with a view to speed, as the chief object desired is to carry passengers and mails quickly from port to port. As the run is only of three hours' duration, it would obviously not pay to enter into any refinements with a view of economizing fuel. The time under way is comparatively small when considered in relation to the time spent in raising steam and cooling down again. This is a point which should be borne in mind, but which some critics appeared to forget during the discussion. Perhaps engineers are apt to base their estimates of efficiency, especially in marine practice, too much on an economy basis. It is a good thing to save fuel if it can be done without too much sacrifice. An examination of the details of the various trials of steamships made by the Research Committee illustrates this important point. We hardly know how to deal with this paper. It is full of information of the most valuable description, but its very fullness renders it extremely difficult to make an abstract, and we have not space to give all the details in full. Perhaps the best plan will be to give some of the leading facts; and, although these may appear somewhat bald standing alone, they will enable our readers to form an estimate of the scope of the trials, and those who are especially interested will go to the original, in the Transactions of the Institution, for fuller details. The *Ville de Douvres* is 271 feet long, 29 feet broad, and 15·5 feet deep, moulded. Her registered tonnage is 855 gross; and her displacement 1090 tons. She was run for nine hours especially for the trial in the North Sea. The engines are of the compound inclined, surface-condensing type, with cylinders 50·12 inches and 97·12 inches in diameter, with 72 inches stroke. Neither cylinder is steam-jacketed, but there is an intermediate receiver encircling the high-pressure cylinder; an arrangement which certainly does not tend towards efficiency. The air, feed, and bilge pumps are driven from the main engines. The circulating pump is separate, and is estimated to develop 47 indicated horse-power. The surface condenser contains 6540 square feet of tube surface, and it is so arranged that the circulating water passes three times through the condenser. The course of the water is such that the coldest water meets the hottest steam. This is naturally not the best arrangement, for the circulating water would still be efficient for taking heat from the hottest steam, even after it had been somewhat raised in temperature by the coldest steam. On the other hand, circulating water having been heated by the steam at highest temperature, will be comparatively inefficient to further cool down steam already cooled to a great extent. In any case, if a good vacuum be ultimately obtained, the refrigerating surface will be far less effective. The paddle-wheels are 22 feet 10 inches over the floats, the latter being 10 feet broad and 4 feet 4 inches deep. The immersion on trial was 17 inches. There are four single-ended return-tube boilers, 13 feet by 10 feet. The grate area is 236 square feet, and the total heating surface 7340 square feet. There is forced draught on the closed stokehold system. The total weight of all machinery, exclusive of paddle-wheels, and all water is 361 tons. Block fuel was used throughout the trial. The calorific value, calculated from analyses made, was 14,390 thermal units per pound. This corresponds to an evaporation of 14·90 pounds of water from and at 212° F. A number of samples of furnace gases were collected and analyzed, with the following mean results:—

	Carbonic Acid.	Carbonic Oxide.	Oxygen.	Nitrogen.
By volume per cent. ...	11·55 ...	0·00 ...	7·95 ...	80·50
By weight per cent. ...	16·84 ...	0·00 ...	8·44 ...	74·72

There was a little uncertainty about the temperature of the chimney gases, but the mean temperature was assumed to be 910° F. The mean draught was equal to a pressure of from 0·92 to 1·22 inches on the water-gauge. A notable feature about these trials was that the feed measurement was made by meters. This is a vast improvement, in one respect at least, and that of great importance, on the measuring tank system. Measuring tanks are always cumbersome and difficult to fit; so much so that they generally prove the greatest bar to proper trials being made of the efficiency of marine machinery. The meters used were of the Kennedy type, and appear to have answered the purpose admirably. There is no trouble in taking a meter reading, whilst the measuring tanks require constant attention. We look on the introduction of the water meter for this purpose as a most important step in advance, and one which will lead to engineers obtaining more frequent information on the efficiency of marine engines. It is most desirable that the performance of the boiler should be separated from that of the engine. The indicated horse-power and coal consumption give the economy of the whole machine; but when results are not satisfactory it is often difficult to say whether the fault rests in the boiler compartment or the engine-room. Another step in advance is the effort made to measure the amount of priming water. In the present day we do not have so much trouble from priming as in past times, when lower pressures were in use and the steam space was practically what it is now. Still, there are yet large quantities of unevaporated water often carried over to the engines by the rush of steam. It is obviously useless to exercise great care in measuring the feed if a considerable part of it is carried from the boiler to the condenser simply as water. In such a case the boiler is credited with a high evaporative efficiency by reason of its very fault; and the engine is debited with steam which it never receives, but on the contrary is having its action impaired by the presence of water in the cylinders. The method of testing for priming is as follows:—A quantity of steam from the main steam-pipe is condensed in a special surface-condensing apparatus, and collected, and at the same time a sample of water is taken separately from the boilers. Both of these samples are carefully analyzed to determine the quantity of salt present in each. As the whole of the salt found in the sample from the steam-pipe must have come over from the boiler in conjunction with priming water, and not with steam, a simple calculation will show how much boiler water corresponds with the quantity of salt, if any, found in the steam-pipe sample. From this it is easy to determine what percentage of the whole feed-water has passed from the boilers in the form of water, or, in other words, what percentage there is of priming. The chemical determination for salt is a very simple one, and is capable of being carried with ease to an exceptional degree of certainty. The observed and calculated data of the trial are given in a full table appended to the report. The mean boiler pressure was 105·8 lbs. above atmosphere, the vacuum 10·12 lbs. below atmosphere, the revolutions 36·82 per minute, the mean indicated horse-power 2977, the fuel per square foot of grate per hour 31·3 lbs., and the feed-water per indicated horse-power per hour 20·77 lbs., allowing for auxiliary engines. The efficiency of the boiler was 66·1 per cent., and of the engines 11·7 per cent. The combined efficiency of engine and boilers was 7·7 per cent.

A very interesting discussion followed the reading of the report, but a great part of this it would be useless to give, as many details of the trial have necessarily been omitted from our brief abstract.

A paper was next read "On Condensation in Steam-Engine Cylinders during admission." This was a contribution by Lieutenant-Colonel English, of Jarrow. In former papers on this subject the author had given experimental data, but it was objected that he had left out of account the range of temperature in the cylinder. In order to show that this was not the case, he submitted the following formulæ, which, he claimed, proved his case. The former papers, a study of which is necessary to a proper understanding of the facts, may be found in the Transactions of the Institution for the years 1887 and 1889.

In jacketed cylinders the weight of steam condensed per stroke and not re-evaporated at cut-off is represented by the expression

$$\frac{56}{\sqrt{\text{revs. per second}}} \times \frac{(S_c - S_1)}{L}\rho_1,$$

where S_c is the unjacketed clearance surface in square feet, S_1 the fresh surface exposed during admission up to cut-off, ρ_1 the initial density of the steam in pounds per cubic foot, and L the latent heat of evaporation in thermal units. If d be the diameter of the cylinder in feet, l the length of stroke in feet, m the proportion of stroke up to cut-off, $\mu = \frac{S_c}{2 \times \text{area of cylinder}}$, and N the number of revolutions per minute; then S_c = unjacketed clearance surface $= \frac{\mu\pi d^2}{2}$; $S_1 = \pi dml$; $\sqrt{\text{revs. per second}} = \frac{\sqrt{N}}{7{\cdot}75}$; and the foregoing expression may be written

$$\text{Weight condensed} = \frac{56 \times 7{\cdot}75}{L \times \sqrt{N}}\left(\frac{\mu\pi d^3}{2} - \pi dml\right)\rho_1$$

$$= \frac{868}{L \times \sqrt{N}}\left(\frac{\mu}{ml} - \frac{2}{d}\right)\frac{\pi d^2 ml}{4}\rho_1.$$

But $\frac{\pi d^2 ml}{4}\rho_1$ is the weight of steam per stroke uncondensed at cut-off, and 868 may be taken as an approximate value for L; therefore for jacketed cylinders;

$$y = \frac{\text{weight condensed}}{\text{weight uncondensed}} = \frac{1}{\sqrt{N}}\left(\frac{\mu}{ml} - \frac{2}{d}\right).$$

For unjacketed cylinders a similar approximate expression is

$$y = \frac{1{\cdot}5}{\sqrt{N}}\left(\frac{\mu}{ml} - \frac{2}{d}\right).$$

The author supported his views by means of a voluminous table, in which he gathered together the observed data on a number of steam-engine trials made by various well-known authorities, to which he attached the results obtained by calculation on his system.

A short discussion followed the reading of this paper, and the meeting was then brought to a conclusion by the usual votes of thanks.

The summer meeting of the Institution will be held at Portsmouth, on July 26 to 29.

THE ROYAL SOCIETY SOIRÉE.

THE annual *soirée* of the Royal Society, which took place on Wednesday, May 4, may be said to have been the most successful that has been held for many years. All the necessary arrangements, which were by no means few in number, were carried out without a hitch, while the exhibits were of a most attractive nature. As regards the latter, the following are a few notes of the most novel and important objects displayed:—

Prof. T. E. Thorpe exhibited a model to illustrate the general phenomena of explosions as brought about by the presence of dust particles, in explanation of the causes of colliery explosions. This apparatus consisted of two long narrow boxes, fitted together in the form of a cross. On the bottom of these boxes was thinly strewn a quantity of fine Lycopodium powder, while at one end of the longer box there was a small chamber in which a blank cartridge was fired. The firing of this cartridge corresponded to the direct action of a "blow-out shot," while the dust raised by the concussion, which carried the flame throughout the entire apparatus, took the place of the fine coal dust. The apparatus also showed that the progress of such an explosion was always accompanied with increase of violence.

Prof. Clowes showed an ordinary miner's safety-lamp which had, by a very simple contrivance, been converted into a delicate instrument for detecting minute proportions of fire-damp. To the ordinary burner an additional tube is made to pass through the oil reservoir, one end of it being connected, by means of a flexible tube, with a small portable bottle of compressed hydrogen. The hydrogen when turned on becomes ignited close to the oil burner, the flame of which is extinguished by turning down the wick; by adjusting the flame of hydrogen to the standard height, a luminous column of light is seen vertically over it, from the behaviour of which the amount of inflammable gas can be directly estimated. At the conclusion of the experiment the wick is simply turned up, and ignited from the hydrogen flame; the latter is then disconnected from the bottle. From 0·25 to 3 per cent. of fire-damp has in this way been estimated, while greater quantities than these have been measured by reducing the size of the flame.

Vacuum tubes without electrodes, exhibited by Dr. Bottomley. These tubes, which were of a variety of shapes and kinds, illustrated very beautifully all the phenomena of stratification. They were sensitive also to magnetic and electro-dynamic influence, and showed the phenomena of molecular bombardment. The brilliant illumination of a piece of Iceland spar contained in a glass sphere afforded an excellent means of displaying the electrical excitements. [For an account of experiments with vacuum tubes, see a letter by Mr. Bottomley in NATURE, January 6, 1881, vol. xxiii. p. 218.]

Mr. Cecil Carus-Wilson exhibited some natural and artificial sands, from which he was able to produce many musical notes. These notes, as he explained, were the results of the rubbing together of the surfaces of the grains of sand, but he had met with several sands from which he could not obtain a vestige of a note. One special artificial sand sang only when rubbed in some sort of vessel.

Apparatus for measuring degrees of incompleteness of colour vision, exhibited by Mr. Brudenell Carter. The object used for the tests is a group of various colours, which were such that they could be seen by either reflected or transmitted light. The amount of illumination that was required to recognize the colours distinctly was a measure of the "degree of incompleteness." In order to control this amount of illumination, light of known intensity had to pass through a variable aperture before it fell on the test object, the size of this aperture being read off in square millimetres.

Captain Weir's azimuth diagram was exhibited by Mr. J. D. Potter. It is claimed for this diagram that besides being most ingenious, it furnishes one of the most successful modes of graphic solution of a mathematical problem that has ever been invented. It is used for finding the true azimuth of a heavenly body, taking into account the ever-changing errors of the compass, which in our days of iron ships have to be so carefully watched and recorded. The errors as usually determined are obtained from observations made of the compass-bearing of a heavenly body (the sun generally being taken) with its true bearing, and it is for the simplification of this method that this azimuth diagram has been found to be practically useful.

Prof. Oliver Lodge had three exhibits. The first was the projection of interference bands on a screen, being produced by a modified method of Michelson. Very striking also were the electric sparks in and to water, illustrating lightning effects and multiple flashes. In a shower, with too great spark-length for a strong discharge, a multitude of violet streams or spurts filled the air, resembling somewhat lightning flashes. The spark to water spread itself out over the surface, showing that the surface layer was a feeble dielectric, while the spark under water was brief but very violent, treating the water as a dielectric, and producing concussion. The electric retina, illustrating the possible meaning of the rod-and-cone structure, was very interesting; radiation from spheres which were in a suddenly disturbed and oscillatory electrical condition falling upon a graduated series of end-on cylinders, which responded by vibrating transversely.

Mr. W. Crookes repeated many of those beautiful experiments of electric currents of high potential and extreme frequency that were first carried out by Tesla. The discharges from a battery of Leyden jars were sent through the primary wire of an oil induction coil. The frequence of alternation amounted to no less than 1,000,000 a second, while the electromotive force reached the enormous amount of 100,000 volts. Perhaps it was as well that this frequency was great, otherwise the physiological action might have been rather surprising to those who trusted implicitly in Mr. Crookes. The resistance offered by the sheet of vulcanite to the strong current produced some fine flashes, while very pretty were the examples of brush discharges, St. Elmo's fires, &c., at the secondary poles of the oil induction coil.

The electrical apparatus shown by Captain Holden, R.A., consisted of some very important new instruments, among which we may mention the high-speed chronographic pen for taking a number of successive records of short intervals of time, the pen being automatically reset after each record; an improved simple compensated voltmeter on the hot wire system, and the dead-beat alternating current ammeter worked by a heated metal strip and free from self-induction.

Prof. Roberts-Austen exhibited a new electrical method for the exact determination of very high temperatures, which has rendered possible the construction of a very simple instrument, devised by Prof. H. Le Chatelier, that can be placed in the hands of any workman. The latter depends on the comparison of the intensity of the radiation emitted by a glowing body (the temperature of which has to be determined) with that of a standard source of light. To use the instrument it is pointed in such a direction as to have the light from the heated mass of metal in its field of view, so that the colour can be distinctly observed; in the same field of view a series of standard colours can also be made apparent (situated side by side with the heated metal), by turning a milled head screw which carries a pointer over a graduated scale. By matching the colours a direct reading of the position of the pointer gives the required temperature.

The Rev. F. J. Smith exhibited an electric tram chronograph which he had devised for measuring small periods of time, varying from one-fourth to one-twenty-thousanth part of a second. This instrument consists of a metal girder furnished with a T-shaped end, carries two steel rails, and is supported on a V-groove, hole, and plane system. The carriage, on which is fixed a slightly smoked glass plate, runs on these rails, driven either by a weight or by a coiled spring. A metal pillar, carried on a V-groove, hole, and plane system, is placed in front of the moving surface, and supports electro-magnetic styli which can be brought into contact with the smoked surface; a tuning-fork also is so placed that the traces are found to be recorded on the smoked plate so as to afford a means of measuring the time intervals. The two motions of the pillar, of rotation and vertical translation, allow a large number of observations to be made on the same plate. There are also continuous contact-breakers, whereby, when a photographic plate is fixed in the carriage, spark photographs of moving objects may be obtained. This instrument has been applied to the measurement of the velocity of projectiles, and small periods of time in physiological research, and to the photography of insects and falling drops of liquids.

Perhaps the most unique exhibit of the evening was the series of photographs of flying-bullets which Mr. Boys had obtained by a modification of an old method. The photographs showed beautifully the waves in the air caused by the rapid flight of the bullet analogous to those produced by a fast-going steamer. In one slide the small pieces of paper through which the bullet had passed were also seen ploughing their way through the air, producing quite as definite waves as the projectile itself, only of not such large dimensions. The passage of a bullet through a piece of wire was also very curious, the piece of wire that was cut off not having time to fall before it was seized by the lightning eye of the camera. The photograph showing a magazine rifle bullet piercing a glass plate brought out some very interesting facts. The glass appeared to be thoroughly scattered in a direction opposite to that in which the bullet was proceeding, the greatest scattering taking place on the side which the projectile touched first. The waves set up on the glass plate gave measures of the wave, length of the tremor caused, and the velocity of travel. The bullets used for these pictures were of various kinds, and the velocities varied from 750 to as much as 3000 feet per second, the former from a pistol and the latter from a magazine rifle, the bullet being composed of aluminium to obtain this great velocity.

The Committee of the Kew Observatory exhibited a testing camera for photographic objectives that had been designed by Major L. Darwin. With this instrument all the most important features of a lens can be accurately and swiftly determined. We may mention here that arrangements are being made that any lens sent to them will be thoroughly examined in all respects under the superintendence of Mr. G. M. Whipple, certificates of examination being made out, as is at present done in the case of other instruments.

We must now pass on to the photographs.

Astronomy was well to the fore with the exhibits of Messrs. Lockyer and Roberts. The former showed a fine spectrum of Nova Aurigæ, that had been enlarged twenty-five times from a negative taken with only a 6-inch object-glass and prism by the Brothers Henry and Hilger respectively; several fine photographs of stellar spectra illustrating the main evolutionary types according to the meteoritic hypothesis, and photographs of the 3-foot reflector at Kensington that is now near completion. Mr. Roberts showed some photographs of celestial objects; the original negative of Nova Cygni, taken with a 20-inch reflector with a two-hours' exposure, showing the Nova as a star of the thirteenth magnitude. An enlargement of the region in which Nova Aurigæ was situated when the star was of the fourth magnitude was also displayed, together with the original photograph taken with the instrument before mentioned, but with an exposure of three hours.

The photographs showing the great sun-spot of February last, exhibited by the Solar Physics Committee, may be said to be the best series that has ever been obtained. The series included nine days, and showed the remarkable changes that occurred during the interval from February 5 to February 17.

Mr. W. Saville-Kent exhibited a series of photographs, over a hundred, taken by himself, enlargements of the same, and water-colour sketches, illustrating coral reefs, coral animals, and the marine fauna generally of the Great Barrier district of Australia. A lantern exhibition illustrating the same subject was also included in the evening's programme. The reef views, which portrayed extensive areas of growing corals of innumerable varieties, were, as explained by the exhibitor, taken at abnormally low spring tides, and are as a matter of fact very rarely visible to the extent depicted. Among the more important points associated with this exhibit were the facts that in a large number of instances accurate measurements had been taken of the individual corals that composed the reefs photographed, such reefs being in easily accessible positions, where their subsequent amount and rate of growth could be periodically determined. This exhibit, more particularly with relation to the illustrations of living coral polyps—those of the mushroom corals, genus *Fungia*, being particularly noteworthy—represented the first occasion in which photography has been systematically applied to this highly interesting biological subject. A second novelty exhibited by Mr. Saville-Kent was a pearl of fine quality and considerable size that the exhibitor had caused the mother-of-pearl shell animal, *Meleagrina margaritifera*, to produce by means of a delicately-manipulated operation on the living animal.

From the Zimbabwe ruins, Mashonaland, some very valuable finds in the shape of pottery, gold crucibles, weapons, ingot moulds, &c., were exhibited by Mr. Theodore Bent and the Royal Geographical Society; while by the same exhibitors were shown a model of the circular temple at Zimbabwe, built of small blocks of granite without mortar; and several plans of ruins in Mashonaland. No less interesting also were the photographs of ancient Central American monuments and buildings from the ruins at Chichén Itzá (Yucatan), Palenque (Chiapas), &c., exhibited by Mr. Alfred P. Maudslay; and a selection from the proof-plates to the first memoir of the archæological survey of Egypt that is being undertaken by Mr. Percy E. Newberry. One of these proof-plates showed all the successive stages of a wrestling match between a black and a white man, more than a hundred different positions being recorded; the white man, we are sorry to say, seemed to be getting the worst of it in many of them.

Several important discoveries were made during the Royal Dublin Society's survey of the fishing grounds on the west coast of Ireland; specimens of several fish then obtained were exhibited by Prof. A. C. Haddon and Mr. E. W. L. Holt. Many new to British waters were found, while one quite new to science (*Nettophichthys retropinnatus*, Holt) was caught.

Some very curious worms composed Mr. F. E. Beddard's exhibit. They were specimens of *Branchiura Sowerbii*, and were found in a tank in the Regent's Park Botanical Gardens.

They possess a dorsal and ventral series of contractile gills, which make them differ from all other known fresh-water worms.

To summarize shortly a few of the other exhibits, we may mention Messrs. Pike and Harris's high tension apparatus; Mr. H. L. Callendar's platinum resistance pyrometers; the original specimen of *Asteropecten Orion* (Forbes), and a specimen of a slab of mountain limestone Bolland showing the passage of a foraminiferal ooze into crystalline calcite, by Prof. W. C. Williamson; Prof. Percy Frankland's crystals of active calcium glycerate (lævorotatory); and the two exhibits of turacin, one by Dr. C. A. MacMunn, showing the very remarkable spectrum it produces; the other by Prof. A. H. Church, who discovered this red pigment in the wing-feathers of certain plantain-eaters or Touracos. A very ingenious process of so-called colour photography was explained by Mr. F. Ives, of Philadelphia, who showed several pictures by means of a special optical lantern.

THE SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY.

THE annual Exhibition of this Society was held on the 5th and 6th inst., at "The Bridge House," London Bridge, S.E. The President, Mr. C. G. Barrett, F.E.S., in opening the Exhibition, gave a short account of the history of the Society from its formation by eleven South London entomologists in 1872; and he referred to the work done by members in rendering popular the study of biological science.

The exhibits were arranged in four rooms, and were very varied, including examples of nearly every order of the animal and vegetable kingdoms.

In the first room Mr. C. S. Cooper exhibited an almost perfect collection of British wild flowers and leaves; the Lambeth Field Club, Mollusca; Mr. J. T. Carrington, land shells from the Riviera, arranged so as to show variation; Mr. C. H. Collings and Mr. D. W. Collings, British and Australian birds' eggs and British birds; Mr. H. J. Turner and Mr. Rice, nests and eggs of British birds, the latter having a double nest of the great titmouse (*Parus major*). The tables around this room were set apart for the exhibition of objects by aid of the microscope, and among so many it is difficult to make a selection; but the more important objects were those of Mr. T. D. Ersser, who showed the circulation of the blood in a gold carp, a most interesting subject; Mr. J. H. Stanley, spawn of perch; Mr. H. Groves, the circulation of sap in Nitella; Mr. R. Macer, heads and eyes of various species of spider; Mr. West, freshwater Polyzoa; Mr. E. Hinton, preparations of the Hydroids, including the beautiful sea pen, killed with the tentacles fully extended; Mr. W. B. Medland, the pulsation in the heart of a snail; Mr. J. B. Medland, a section of the jaw of a mole, with the teeth *in situ* (polarized).

In the second room Mr. J. A. Cooper's birds' nests and eggs in natural clutches occupied one end, and were much admired: one of the principal features of this collection being that it is arranged to show the variation in different clutches of the eggs in one species. This was particularly noticeable in those of the red-backed shrike. Among the eggs there were white varieties of those of the chaffinch, lapwing, and great black-backed gull; variable series of the guillemot, razorbill, lapwing, and golden plover; also a series of nests containing eggs of the cuckoo, including nests of the wagtail, tree pipit, chaffinch, greenfinch, hedge sparrow, robin, flycatcher, yellow bunting.

In the class Insecta some of the more important exhibits were those of Mr. J. H. Leech, with sixteen drawers containing Palæarctic Lepidoptera. This collection attracted considerable attention. Mr. J. Jenner Weir showed exotic Rhopalocera, illustrating forms of mimicry, and fine examples of South African Ornithoptera. Mr. S. Edwards also contributed a large exhibit of exotic Rhopalocera. Adjoining these, was the Society's typical collection of Canadian Lepidoptera. Four drawers of European Neuroptera were shown by Mr. R. McLachlan. Mr. H. Moore exhibited a number of wasps' nests. Mr. T. R. Billup's exhibit comprised British Coleoptera, containing types of nearly all the known species; three drawers of Hemiptera-Heteroptera and one of Homoptera were beautifully arranged, and the adoption of a system of labelling giving the name of the species, the locality where taken, and date of capture, is much to be commended; seven drawers of Hymenoptera Aculeata, containing many rare species, also long series of Ichneumonidæ, many of the specimens being new to science, and others new to Britain; also two drawers of life-histories of Hymenopterous and Dipterous parasites, together with the larvæ and imagines of the Lepidopterous host. This last exhibit was one of the most interesting and instructive of the exhibition. Of British Lepidoptera there was a magnificent display, there being some forty exhibitors. Mr. R. South showed nearly the whole of his collection of *Pyrales*, *Crambi*, *Pterophori*, and *Tortrices*, a selection of *Noctuæ*, among which were extreme series of most of the polymorphic species in the group; a drawer of *Lycæna icarus*, showing the colour range of both sexes, one very blue female without black discoidal spots was especially interesting; a drawer of Geometræ showing that the colour and ornamentation of the female parent is transmitted to a large proportion of her offspring; Mr. C. G. Barrett, *Pieris napi*, one female of a light canary-yellow colour from Norfolk, others suffused with grey from South Wales, others with black spots and tips and dark nervures from the north of Ireland; varieties of *Anthocharis cardamines*; long series of *Odonestis potatoria*, showing extreme variation, the colour in the males ranging from chocolate to a pale buff; also extensive series of varieties of *Agrotis cursoria* and *A. tritici*, from the east coast of England. Mr. Barrett also exhibited a drawer of varieties of Rhopalocera lent to him for the purpose of figuring in his book on the British Lepidoptera, by the Rev. Joseph Greene, the Rev. O. Pickard Cambridge, Dr. Wheeler, Mr. J. E. Robson, Mr. E. Sabine, and Mr. Sydney Webb. It is doubtful whether such a collection of varieties has been seen before, and those Lepidopterists who pay special attention to the question of variation were much interested in the extraordinary varieties shown. Mr. F. Merrifield, examples of *Selenia illustraria*, *S. illunaria*, *S. lunaria*, *Eugonia alniaria*, *Vanessa urticæ*, *Platypteryx falcataria*, *Arctia caia*, *Bombyx quercus* and var. *callunæ*, bred by him in his experiments on the effect of temperature on the pupæ of certain species in causing variation. Labels were attached to each specimen showing the conditions to which the pupæ had been subjected, and the results obtained from these. It appeared that a lower temperature produced examples which were darker and more intense in colour than those subjected to higher temperatures. A third drawer of *S. illustraria* and *S. illunaria* was shown, as illustrations of the effect of temperature applied for a very few days to pupæ at a sensitive stage, *i.e.* just before they began to show the colour, the forcing temperature was about 77°; the natural temperature about 40° to 50°; a range of 15° or less (at a point which it appeared was not yet actually ascertained between 57° and 73°) was sufficient to produce the full temperature effects shown in the first two cases, but a range of much less than 13°, if at the right part of the thermometric scale, produced substantial difference of colouring. Mr. W. Farren contributed examples from Cambridge including fine yellow specimens of *Bryophila perla*, and extensive series of *B. muralis* and *B. impar* of Warren; these gave rise to considerable discussion among visitors as to whether *impar* was a true species or only a variety of *muralis*. Mr. R. S. Standen, a small box showing extreme varieties of *Argynnidæ*. Mr. Tugwell, a selection from his cabinet, including long series of *Eugonia alniaria*, Esp., melanic forms of *Phigalia pedaria*, *Boarmia repandata*, *Tephrosia biundularia*, &c., and striking varieties of *Abraxas grossulariata*. Mr. C. G. Gregson also put in a magnificent series of varieties of this last-named species, some of the specimens being entirely suffused with the black markings, in others the yellow-coloured markings were wanting, and many were very pale forms, the black markings being absent; Mr. Gregson also showed *Dianthœcia conspersa*, from various localities, to illustrate the local variation in that species—many of the forms were so extreme that he had given them varietal names. Mr. J. R. Wellman, his collection of Dianthœcia and Acidalia, also a drawer of *Cidaria russata*, bred and captured from various parts of Great Britain, a most interesting drawer as showing local variation. Mr. F. W. Hawes, Rhopalocera, reared in 1890 and 1891, chiefly from ova obtained by searching or from the captured female, thus enabling Mr. Hawes to ascertain the early life-histories of this group; among them were examples of *Hesperia lineola*, the species recently added to the British list by Mr. Hawes. Variation in *Arctia caia* was shown by Mr. Goldthwait, Mr. T. W. Hall, and Mr. A. Mera. Mr. C. H. Williams included in his series a gynandrous specimen of *Argynnis paphia* taken by him last summer in the New Forest, and much attention was paid to this beautiful specimen. Life-histories, the larvæ being mounted on the natural food-plant, were shown by Mr. J. A. Simes, Mr. A. Quail, and Mr. A. J. Croker, the latter gentleman's *Phorodesma smaragdaria* being especially noticeable. Mr. R. Adkin exhibited a collection of British Sphinges and Bombyces, arranged with a view to showing local variation, such variation being well defined in some of the species of the genus *Spilosoma.* Also a collection of Macro-Lepidoptera made at Rannoch, Perthshire, in 1891, illustrating an article on the local variation prevailing in that district recently contributed to the *Entomologist.* Mr. Tutt, extremely long and variable series of Noctuæ. Mr. Machin four drawers from his cabinet; among the rarer species were *Dicranura bicuspis* and *Drepana sicula.*

In the third room there was a large exhibit of marine Mollusca, by Mr. Conisbee. Mr. Step's exhibit of living Mollusca afforded a capital opportunity for comparing the mollusks as well as their shells. Between thirty and forty species were thus shown, each in a separate glass, and ranged from the substantial *Helix pomatia* to the graceful *Clausilia rugosa* among land snails; and from the large *Anodons* to the fragile *Planorbis linentus* among the aquatic species. Pond life was shown by Mr. Perks; living newts, &c., by Mr. R. Adkin, Jun.; and living snakes, &c., by Mr. Gee. A gigantic sponge was exhibited by Mr. Kedgley.

In a fourth room Mr. Reeves exhibited and explained an original set of diagrams, showing the correct positions of horses' legs while walking, trotting, and galloping, and to demonstrate their correctness the diagrams were transferred to a zoëtrope.

A large room was set apart for lectures, and during each evening crowded audiences listened to Mr. F. Enock, who lectured on "The Life-history of the British Trap-door Spider." The lecture was illustrated by Mr. Enock's original microphotographic slides, shown by means of the oxy-hydrogen lantern. Mr. E. Step's "Talk about Toadstools" was listened to attentively on each evening. The figures thrown on the screen were from Mr. Step's own photographs and drawings. A third lecture was given by Mr. George Day, illustrated by microphotographic slides, entitled "Domestic Friends and Foes."

IMÈRINA, THE CENTRAL PROVINCE OF MADAGASCAR.

ON Monday evening the Rev. James Sibree read a valuable paper on Imèrina, the central province of Madagascar, before the Royal Geographical Society. After an account of the work of recent explorers, of whom the French surveyors, MM. Catat and Maistre, and the English missionary, Mr. Baron, are the most important, Mr. Sibree came to the main subject of his paper, of which the following is an abstract.

M. Grandidier, who is now completing a splendid atlas of Madagascar, published a map of Imèrina on the scale of 1 : 200,000 in 1880, and in 1883 an orographical map coloured according to the contour lines. The road from the port of Tamatave to Antananarivo, the Hova capital, in the centre of the Imèrina province remains a mere footpath, impassable either to wheeled vehicles or to beasts of burden; and now, as 300 years ago, porters are the only means of transport.

Imèrina ("the elevated") is bounded on the east by the steep ridge of forest-girdled mountain sloping to the Indian Ocean. The other boundaries are indistinct, and the total area of the province may be estimated at 7000 square miles. The general level of the province is from 4000 to 4500 feet above the sea. It is a mountainous region, abounding in peaks, which rise high above the breezy plateau, and marked also by many valleys. The most prominent summits are Angàvokèly to the east, Ambòhimiangàra in the extreme west, Ihàranandriàna to the south, Milangàna, Ambòhimanòa, and Andrìngitra more central, and Ambòhipanìry and Vòhilèna to the north. The south-west of the province is dominated by the central mass of Ankàratra, a denuded volcano of great size, its peaks forming the culminating points of the island, and reaching nearly 9000 feet above the sea. The mountain-peaks are usually granite or gneiss, sometimes occurring in great rounded bosses, sometimes in fantastically carved pinnacles resembling from a distance Titanic forts, castles, and cathedrals. Decomposed granite covers a great part of the country with thick deposits of clay, sometimes white but more often tinted deep red by ferric oxide. Iron is abundant, gold has recently been discovered, graphite, galena, copper, and other useful minerals are also found in Imèrina. The watershed of the island lies much nearer the east coast than the west, and the two chief rivers rising in the extreme east traverse the breadth of the province on their way to the Mozambique Channel. The Ikòpa, fed by the Sisaony, the Andròmba, the Màmba, and other streams, flows north-westward through the fertile plain of Bètsimitàtatra, and farther north is joined by the Bètsibòka, under which name the united stream runs on to the sea at the Bay of Bembatòka. Lake Itàsy is the only large body of water in Imèrina, and probably owes its origin to volcanic subsidence.

On account of its altitude Imèrina has a pleasant temperate climate, although lying within the tropics. The south-east trade-winds, blowing fresh and moist over the forest belt and the wooded plains of the east, make the atmosphere peculiarly bracing in the cooler season. The annual rainfall at Antananarivo is about 53 inches. Through the clear pure air distant landscapes stand out with remarkable sharpness of outline. Towards sunset Imèrina is seen in its most attractive aspect; the hills, range beyond range, assume the richest shades of purple, the sky flames with crimson and gold, and the long clay walls of the native compounds glow like streaks of vermilion.

The general aspect of the province is bare, except for patches of primæval forest in the northern districts. Moor-like hills, which would look utterly dreary but for the marvellous atmospheric effects, predominate. Near Antananarivo the dried-up bed of an ancient lake, known as Bètsimitàtatra, forms a great plain, covered with rice-fields, which support a dense population. The steep sides of the river valleys are terraced, like great green staircases, with rice-plots, where the grain is sown broadcast, and whence the young plants are transplanted in the larger fields along the river-plains and in the meadows left by dried-up lakes.

The political subdivisions of Imèrina are mainly tribal, and are used for purposes of taxation, and for the apportionment of military levies and forced labour. No census has been taken, but an estimate based on the number of villages and houses justifies the estimate of the population at about 1,100,000. Except Antananarivo, there are only small villages in the province, but these are clustered very closely together, especially to the north and north-west of the capital. Several of these were formerly tribal capitals, and Ambòhimànga still retains nominal equality with Antananarivo in royal speeches. The old villages were always built on hills for purposes of defence, and surrounded by double or treble lines of fosses and embankments dug out of the hard red clay. A narrow bridge of the red clay leads to the gateway, which is formed of blocks of rock, either a circular slab 10 or 12 feet in diameter, which was rolled between upright gate-posts so as to block the way, or massive upright monoliths bearing strong wooden gates. In recent times the Hovas have largely deserted these fortresses, and built themselves villages close to the rice-fields. Graves of the aboriginal Vazimba are scattered over the province, but local feeling prevents any examination of these from being made.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, May 2.—M. d'Abbadie in the chair.—The movements of minute organisms analyzed by means of chronophotography, by M. Marey. Using an arrangement described in the *Revue Générale des Sciences* in November last, and in NATURE, vol. xlv. p. 228, M. Marey has obtained photographs of the movements of blood corpuscles in the capillaries, and has analyzed the movements of zoosphores in the cells of a Cladophora. Enlargements from these negatives have been presented to the Academy. By taking a series of pictures at intervals of about one-tenth of a second, and projecting them upon a screen at about the same rate, the effect of the real motions of the object can be reproduced. The arrangement for doing this will be described in a future communication.—Observations of Swift's, Denning's, and Winnecke's comets, made at Algiers Observatory with the *coudé* equatorial, by MM. Rambaud and Sy. Observations of position are given.—On the approximation of functions of very large numbers, by M. Maurice Hamy.—On the tautochronism in a material system, by M. Paul Appell.—On the laws of electrolysis, by M. A. Chassy. When a substance having the formula M_pR_q is electrolyzed, M designating an electro-positive and R an electro-negative radicle, one equivalent of the radicle R, and $\frac{p}{q}$ equivalents of the radicle M are disengaged when one equivalent of hydrogen is set free in a voltameter included in the circuit. Wiedemann and others have found exceptions to this law, for in the case of some salts, $\frac{q}{p}$ equivalent of the radicle R and one equivalent of the other radicle are disengaged. M. Chassy proposes to substitute the following law for those previously enunciated, all cases being included in it: "Lorsqu'on électrolyse une substance quelconque il se dégage toujours l'équivalent d'hydrogène ou la quantité correspondante du radical électropositif."—A new case of abnormal solution: saturated solutions, by M. F. Parmentier. The author finds that the solubility of ethyl bromide in ether decreases rapidly with increase of temperature.—The occurrence of fluorine in different varieties of natural phosphates, by M. Ad. Carnot. From the results of the analyses of a number of sedimentary phosphates it is concluded that in the sedimentary phosphates the proportion of fluorine is sensibly equal to that in apatites having an equal percentage of phosphorus. Phosphorites of fibrous, semi-crystalline structure have almost the same composition as crystallized apatites. Earthy or compact phosphorites contain a less proportion of fluorine. Concretionary, zoned, and mammillated phosphorites contain barely any fluorine.—Estimation of small quantities of carbon monoxide by means of cuprous chloride, by M. L. de Saint-Martin.—Thermal study of the value of the replacement of hydrogen in phenolic hydroxyl, by M. de Forcrand. C_6H_6O sol. + Na sol. = $C_6H_5 . ONa$ sol. + H gas . . . . + 39·10 cal. This is practically the mean value for the replacement of H by Na in tertiary alcohols and acids, for $\frac{27·89 + 50·17}{2} = + 39·03$.—On an ethylnitroketone and an acetylnitroketone derived from camphosulphophenols, by M. P. Cazeneuve.—Determination of the surface of ebullition of normal paraffins, by M. G. Hinrichs.—Action of pyridine bases on certain sulphites, by M. G. Denigès. THE TELL EL-AMARNA TABLETS IN THE BRITISH MUSEUM.

The Tell el-Amarna Tablets in the British Museum, with Autotype Facsimiles. (London: Printed by order of the Trustees, 1892.)

DURING the summer of 1887, a woman belonging to the household of one of the "antica" dealers who live at or near Tell el-Amarna, in Upper Egypt, set out to follow her usual avocation of digging in the sand and loose earth at the foot of the hills for small antiquities. Every man, woman, and child in the neighbourhood spent, and probably still spends, a large portion of each day in this profitable pursuit, for in the winter season they were able to sell at good prices the scarabs, rings, fragments of beautifully glazed Egyptian porcelain, and other objects of this nature, of which there seemed to be an endless supply in the ground round about. From the time when Wilkinson made his first journey to this place, until quite recently, every traveller who has visited the spot has been able to bring away with him interesting and important antiquities, which have either revealed new facts in Egyptian history, or have served to illustrate and explain processes in the technical arts known to the Egyptians. In the early years of this century, when the scientific staff attached to Napoleon's expedition to Egypt was compiling the materials for the splendid map of Egypt afterwards edited by Jacotin, it was noticed that the "ruins of a large town" existed at Tell el-Amarna, and it is said that a superficial search made over this part of the country resulted in the finding of a number of fine objects which have since filtered into several European collections of Egyptian antiquities. But whatever things have been dug out from these ruins, or from the ground round about them, or however great their importance, nothing possessing the historical and scientific value of the antiquities discovered by the Tell el-Amarna woman in 1888 hath ever rewarded searcher before. The exact details of her search will never be known, neither can the exact spot where she made her great discovery be identified (for the Arabs took care to obliterate all traces of the diggings made by them on the spot after her "find"), but it is certain that in a small chamber at no great depth below the surface, she found a number of clay tablets the like of which had never been before dug up in Egypt. The number of these tablets and fragments is variously given, but it seems that the outside limit may be set at three hundred and thirty; in this matter, however, and indeed in making any statement which is based upon the word of many sellers of "anticas" in Egypt, the writer (and the reader) must protect himself by saying after the manner of the pious Muhammedan, "But God knoweth." Of this "find" the Trustees of the British Museum secured eighty-two tablets, the Gîzeh Museum in Egypt about sixty, and the Berlin Museum about one hundred and sixty pieces, of which a large number are fragments which give no connected sense. The authorities of this last institution published the texts from their own collection together with those from the tablets at Gîzeh by lithography under the editorship of Drs. Abel and Winckler, but the results already gleaned by scholars from this edition appear to be meagre when compared with the quantity of material which the originals offer for study.

The Tell el-Amarna tablets are different from all other known cuneiform documents. They lack the symmetrical form of the tablets from the libraries of the old Babylonian temples, or of those from the library at Kouyunjik, founded by the mighty kings of the last Assyrian Empire—Sargon, Sennacherib, Esarhaddon, and Assurbanipal; the material is, in many cases, ill-kneaded, and contains fragments of flint or other coarse materials; the colour of the clay varies from a light to a dark dusk tint, and from a flesh colour to dark brick-red. They are written in a hand which, to some extent, resembles the Neo-Babylonian writing used commonly in Babylonia and Assyria for about seven centuries before Christ. It possesses, however, characteristics different from those of any other style of cuneiform writing of any period now known to exist, and nearly every tablet contains forms of characters which have hitherto been thought peculiar to the Ninevite or Assyrian style of writing. The large, bold hand found upon some of the tablets suggests the work of the unskilled scribe, but more careful examination shows that it is the result of unconventionality rather than ignorance. The details of the peculiarities of spelling need not be discussed here, but the expert will find many rare and important examples of Assyrian orthography never dreamt of before. The Semitic dialect in which the tablets are written is very closely related to the Hebrew of the Old Testament, and the "Canaanite" forms of pronouns, &c., are of peculiar interest for the student of the Bible, for many of them are new, and they afford the means of explaining certain difficulties which now exist in Semitic grammar. Although these tablets offer a satisfactory solution of some difficulties, they raise many questions which will probably remain unanswered for some time, and among these there is one, not the least important, of how it happens that a governor of Egypt, who was a vassal, and ruling in Syria, should bear the name of Itagamapairi, which is neither Semitic nor Egyptian?

The Tell el-Amarna tablets are unique as an archæological "find," and they are also unique as a means of weaving together the threads of the histories of two or three of the greatest nations of antiquity at a critical period. As we are able to say, with comparative certainty, that they were all written between the years 1500–1450 B.C., they have an authority possessed by few of the documents coming down from this remote period. They partly fill, moreover, a gap in the history of the dynasties of Mesopotamia and Syria, for although much comparatively is known concerning the period in which the Assyrian Empire was founded—about B.C. 1800—and although we have annals of many kings between B.C. 1320 and 620, the history of the period between B.C. 1800 and 1320 is almost unknown.

The Tell el-Amarna tablets in the British Museum consist of a series of despatches written from kings of Babylonia, Alashiya, Mitani, Phœnicia, Syria, and Palestine to Amenophis III., and to his son, Amenophis IV., frequently named Khut-en-aten, or Khu-en-aten, and the "heretic king"; among them also is the draft of a despatch from Amenophis III. to a king of Karaduniyash. Many of them are of a personal and private nature, and these are, of course, the most interesting, for they reveal details of the family life of the great kings of the East, which the ordinary inscriptions have failed to preserve for us; the remainder refer to State business, and show beyond all doubt how close was the connection between the kings of Babylonia, Mitani, and Karaduniyash and the kings of Egypt, and also how great was the commerce and intercourse between these countries. It will be remembered that the Egyptians gained their first foothold in Syria under Amasis I., who, about B.C. 1700, brought the war of independence to a successful close, and marched into Sharuhen, a city to the south of Gaza, mentioned in Joshua xix. 6. His successor, Amenophis I., made no further advance into Syria or Mesopotamia; but Thothmes I., about B.C. 1633, marched into Northern Syria, called Ruthen, and set up a tablet to mark the limit of the frontier of Egypt. His son made no attempt to "enlarge the borders" of Egypt in this direction, and the "wild woman" Hatshepset was too much occupied with fitting out her expedition to Punt to trouble about such things; but when Thothmes III. ascended the throne of Egypt, about B.C. 1600, he at once set out to crush the rebellion which had broken out all over the country to the north-east of Egypt. Making his way by the peninsula of Sinai, he passed into Syria, and within a month from the time he set out he defeated the rebels, whose head-quarters were at Megiddo, and captured the city. During the next few years he marched through the country round about, carrying off spoil, and establishing the worship of Amen-Rā and other Egyptian gods in the principal cities. At a city on the Euphrates called Ni, he set up a tablet near one set up by his grandfather several years before, and it is clear that his hold upon Western Mesopotamia was no shadowy power. Indeed his conquest of the city of Ninip, and the worship of the gods of Egypt established there by him, is referred to by the inhabitants of that place when they write to Amenophis III. more than one hundred years later. When Amenophis III. ascended the throne of Egypt about B.C. 1500, he was, thanks to the bloody victories of his predecessors, able to assume the sovereignty of Western Mesopotamia and Syria without much fighting, and it seems that his expeditions to these parts were undertaken as much for the sake of the lion hunts which he conducted there as for the purposes of conquest. He boasts on his scarabs that in the first ten years of his reign he slew 102 lions with his own hand. That the country of Mitani offered fine opportunities for sport we know from one inscription which says that Thothmes III. slew 120 elephants there; and Tiglath-Pileser I. (B.C. 1120) boasts in his annals that on foot he slew 120 lions with his own hand in Mitani (Rawlinson, "Cuneiform Inscriptions," i. pl. 16, 76–79). While on one of these semi-warlike expeditions he fell in love with a fair-haired, blue-eyed, graceful girl named Thi, the daughter of parents whose names were Iuaa and Thuaa, and she was brought to Egypt in the tenth year of the king's reign, accompanied by another wife of Amenophis, and 317 of her ladies. Thi was evidently the Egyptian monarch's favourite wife; she became *par excellence* the "Queen of Egypt," and her son Amenophis IV. became King of Egypt. Amenophis III. also married a sister and daughter of Kallimma-Sin, King of Karaduniyash, and made proposals for another of his daughters, named Sukharti, while she was still a child, and he took to wife also the sister and daughter of Tushratta, the King of Mitani. A letter from Burraburiyash also reveals the hitherto unknown fact that his son married a daughter of the King of Egypt. One of the most interesting of these tablets is the draft of a letter from Amenophis III. to Kallimma-Sin, King of Karaduniyash, a country conterminous with Assyria; it is the only known letter of Amenophis in Babylonian, and is written upon a tablet of Nile mud. The subject of the letter is a proposal for the hand of Sukharti, whose father, Kallimma-Sin, writes back to Egypt asking what has become of his sister who married the King of Egypt many years before? In reply to this Amenophis invited Kallimma-Sin to send messengers to see and to converse with the lady, and to carry back news of her to her brother. An embassy was sent to Egypt, but its members were too young to be able to remember what the lady had been like, and they failed to identify her satisfactorily. Kallimma-Sin is not unwilling to discuss the marriage of his younger daughter Sukharti, but he points out that he usually gives his daughters to the "kings of Karaduniyash," who make handsome presents to himself and his messengers. Not to be defeated in his desire by the paltry question of gifts to the wife's relatives, Amenophis says that he is not only willing to give for Sukharti as much as all the other suitors could or would give put together, but he will send a gift to Kallimma-Sin in honour of this king's sister, who is now living with him in Egypt. This point satisfactorily settled, Amenophis proceeds to discuss the proposal of Kallimma-Sin for an Egyptian princess, and he plainly but forcibly tells him that "the daughter of the king of the land of Egypt hath never been given to a 'nobody.'" Kallimma-Sin replies, "Why not? Thou art king, and canst act as thou pleasest"; but, willing to be satisfied with a lady of less rank than a princess, he adds, "Surely there be daughters of nobles who are beautiful women in Egypt. Now, if thou knowest a beautiful lady, I beseech thee to send her unto me; for who here could say that she is not a princess?" What Amenophis finally arranged for "his brother Kallimma-Sin" we know not, but it seems that he gave him a large quantity of gold, and that he married Sukharti after all. The letters of Burraburiyash to Amenophis III. are scarcely less interesting, for they refer to old intrigues of the Canaanites, to commercial treaties, and they give some account of this king's gifts to the daughter of Amenophis who was about to marry his son.

The most important correspondent of Amenophis in the land of Mitani was Tushratta, whose sister and daughter he married, and who writes to his son-in-law with a mixture of affection and avarice amusing to contemplate. For example, having acknowledged the receipt of a letter from Amenophis, and said that its "contents pleased him so greatly that even if it were possible to dissolve all the friendship which had existed between them in times gone by, the words of this message alone would, for himself, suffice to re-establish their friendship for ever," he next begs him to send him much gold, and artfully refers to a gold libation bowl and vessels profusely decorated with gold ornaments which Amenophis had sent to his father, thereby hinting that similar gifts would be most acceptable to himself. In true Oriental fashion he says, "When my brother has sent the gold, if I ask, 'Is it enough?' the answer may be, 'Fully enough'; or I may ask, 'Is it the full amount?' and the answer may be, 'It is more than the full amount.'" In the latter case Tushratta declares that he will be "very glad"! In another letter Tushratta gives an account of his accession to the throne. It appears that when his father Shutarna died, his brother Artashumara became king, but was shortly after slain by rebels. Though quite young, Tushratta rallied his friends and supporters, and after some trouble succeeded in slaying his brother's murderers. Facts of this nature are of great importance for restoring the history of this long-forgotten country. It is an interesting fact that together with such letters there always arrived gifts, which consisted of horses, chariots, gold vessels, ornaments made of gold and lapis-lazuli, eunuchs and ladies for the king's household; and the relatives of the Mesopotamian princesses who had become wives of the King of Egypt never forgot to send them gifts of earrings of gold, choice oil for anointing, &c. Sad to relate, however, some of the writers of these letters complain that Amenophis did not send them gifts in return. In a third letter Tushratta mentions that the goddess "Ishtar of Nineveh, lady of the world," had gone down into Egypt during his own reign and during that of his father, and he begs Amenophis to increase the worship of this goddess in Egypt tenfold. A fourth letter of Tushratta is sent to the "Queen of Egypt," who can be none other than the blue-eyed, fair-haired Thi.

Passing from the letters which refer to Amenophis's marriages contracted with Mesopotamian princesses, we come to those relating to the matter-of-fact business of the Egyptian Government of that day. These consist of reports of disasters to the Egyptian power and of successful intrigues against it, coupled with urgent entreaties for help, pointing to a condition of distraction and weakness in Egypt and her dependencies. Some of them must have been addressed to Amenophis III. towards the close of his long reign of about thirty-six years, but the greater number clearly belong to the reign of his son Amenophis IV., for the disorganized condition of the Egyptian provinces in Phœnicia and Syria which they reflect could only have come into existence when Egypt herself was torn by the rival factions which sprang up when that king endeavoured to substitute the worship of the Disk for that of Amen, the mighty god of Thebes. The chief cities of Phœnicia, Tyre, Sidon, Byblos, Aradus, and Simyra (which commanded the road to Aradus), representing the Egyptian power, were being daily attacked by the ever-increasing forces of the enemy, who, seeing the impotence or supineness of Egypt, grew bolder and bolder. Nor did the brave and loyal defence of such men as Rib-Adda, governor of Byblos, and Abi-Milki, King of Tyre, stave off for long the overthrow of the Egyptian power in Phœnicia. The desperate position of this latter loyal officer is almost pathetic in its hopelessness. In one letter to the King of Egypt he says, "My lord, my sun, my god, seven times and seven times do I prostrate myself at the feet of the king, my lord. I am the dust beneath the feet of the king, my lord, and that upon which he treadeth. O my king and lord, thou art like unto the god Shamash and to the god Rimmon in heaven. Let the king give counsel to his servant. Now the king, my lord, hath appointed me the guardian of the city of Tyre, the 'royal handmaid,' and I sent a report in a tablet unto the king, my lord; but I have received no answer thereunto." He then announces the delivering of the city of Simyra into the hands of Aziru the rebel, by Zimrida, governor of Sidon, who had also captured the city of Sazu, wherefrom Abi-Milki drew his supplies of wood and water, for neither existed naturally on [the bleak rock of Tyre; in consequence many Tyrians died of want. Moreover, Zimrida, Aziru, and the people of Aradus attacked the forces of Abi-Milki in chariots by land and in ships by sea. In conclusion he sadly adds, "I am surrounded on all sides with foes, and I have neither wood to warm myself, nor water to drink; I send this tablet to the king by the hands of a common soldier, and may the king send me an answer speedily." When his condition becomes more desperate he sends another despatch, and with it a gift of five talents of copper, hoping thereby to extort an answer from the king of Egypt; in this he reports events with a Cæsar-like brevity thus:—"The king of the land of Danuna is dead, and his brother has succeeded him; there is peace in his land. One half of the city of Ugarit has been destroyed by fire. The soldiers of Khatti have departed Itagamapairi of Kadesh and Aziru have rebelled, and are fighting against Namyawiza. Zimrida, governor of Sidon and Lachish, is gathering together ships and men."

A letter of considerable importance is that of Akizzi, governor of Katna (Çana), for it refers to the origin of the worship of the sun in Egypt. It appears that the King of Khatti came to Katna, and carried off the image of the Sun-god, and Akizzi writes to Amenophis III., asking for money to ransom the image; he makes his appeal on the ground that Shamash the Sun-god, the god of his fathers, became also the god of the ancestors of Amenophis, and that they called themselves after his name. Now this clearly has reference to the title "son of the Sun," which was adopted by nearly every king of Egypt, and indicates that Akizzi believed that the worship of the sun was introduced into Egypt from Asia.

Space forbids our quoting more from these interesting documents, but sufficient has been said above to show what an important contribution to our knowledge of Oriental diplomacy about 1500 B.C. the Tell el-Amarna tablets offer. Incidentally they reveal many new facts of history; they offer a new field for the researches of the geographical student, and the identification of many towns and countries mentioned in the Bible and in the Egyptian inscriptions has already been obtained; they give us for the first time the names of Artatama, Artashumara, and Tushratta, kings of Mitani, and of Kallimma-Sin, king of Karaduniyash; they supply the reasons why and show how the Semites came to have such power in Egypt; and depict the inevitable anarchy which prevails in dependencies or colonies when the dominant power totters or declines.

We have already said that the Tell el-Amarna tablets are different from any other cuneiform documents known, and it is precisely this difference which has made their publication a difficulty. To make a satisfactory edition of these texts it was necessary to unite the skill of the Assyriologist with the accuracy of the photographer, for the former could only transcribe the characters more or less accurately, being powerless to give their exact shape and form, and the latter, while reproducing their exact shape and form, could only show the characters on the flat-sided tablets, those on the rounded edges remaining invisible. The Trustees of the British Museum, then, decided to print in cuneiform type a full transcript of the texts in characters as closely resembling the originals as possible, and in addition to give a number of characteristic specimens reproduced by the autotype process, so that the student who is unable to visit the Museum may be able to make himself thoroughly acquainted with the various complex and unusual forms of characters in which these tablets are written. In addition to the printed texts and autotype plates, a summary of the contents of each tablet is given, accompanied by notes, chiefly philological and geographical, which we believe will be of use to the reader. The summary is preceded by an introduction, in which the finding of the tablets and many points of interest concerning them are discussed in brief paragraphs. It will be remembered that some thirty years ago, when Sir Henry Rawlinson began to publish his monumental work, the "Cuneiform Inscriptions of Western Asia," he contemplated adding translations of all the texts given therein. It was, however, found impossible to do this satisfactorily; and notwithstanding Sir Henry's thirty years' additional labour on the Assyrian inscriptions, it would still be somewhat rash to publish word-for-word translations of such difficult texts as those from Tell el-Amarna. Plain, historical narrative, like the great Tiglath-Pileser inscription, could be and was well enough rendered into English by Sir Henry Rawlinson so far back as 1857; but letters and despatches of a new kind, containing words and forms hitherto unknown, cannot be thus treated. The summary of each tablet will tell the general reader what the tablet is about, and will help the student more than a literal translation of the verbose Oriental phrases would have done. In publishing these texts with autotype reproductions and summaries of contents, the Trustees of the British Museum have made a new departure, and we believe that the edition will be as useful to the general student of antiquity as to the cuneiform expert.

A TEXT-BOOK OF PHYSICS.

A Manual of Physics. By William Peddie, D.Sc., F.R.S.E. (London: Baillière, Tindall, and Cox, 1892.)

THE attempt made by Dr. Peddie to supply a manual of physics suitable for English students and English teachers is altogether worthy of praise, and his effort has undoubtedly been, on the whole, successful. The best works at present in use in higher schools and in colleges as text-books of physics are the well-known English translations of two French books, Ganot and Deschanel. These are, no doubt, excellent books in their way, and in the hands of able English translators the original French compilations have received great improvement. A recommendation also of these French books is to be found in the beautiful diagrams and pictures of experimental apparatus. These we miss in every English book, including the book before us. Nevertheless, even the modified and improved English translations are not altogether satisfactory for English teaching purposes, and Dr. Peddie's work, supplying a need which is very generally felt, will be most warmly welcomed.

The subject has been, on the whole, judiciously treated. It is compressed in an admirable way into very moderate compass. If, now and then, one feels regret that some particular portion has not been more fully dealt with, reflection on the moderate size of the book, and on the way in which each part is treated in the space prescribed to it by the author, often affords a timely and sufficient consolation.

While speaking about size and form, it may be remarked that the paper, the printing, and the binding, make this a pleasanter text-book to hold and to use than any which has appeared for many a day. In this respect the book can scarcely be too highly praised.

Commencing with four preliminary chapters, in which general laws are stated and explanations given as to certain necessary mathematical ideas and formulas, the author proceeds in chapter v. to the treatment of elementary kinematics; and in chapter vi. to the general principles of dynamics, including the general equations of fluid motion and of the equilibrium of a fluid. It is needless to say that these subjects are very briefly touched upon; but teachers will at any rate find a very succinct indication, to say the least, of the parts of mathematics and of dynamics which are most essential to a proper understanding of the physics which is to follow.

Chapters vii. to xiii. inclusive are devoted to properties of matter: general properties of solids, liquids, and gases are dealt with; a good account of gravitation is given; elasticity, diffusion, and the allied subjects, as well as cohesion and capillarity, are discussed; while in chapters xii. and xiii. we find a very fair account—short, of course—of atomic theories, including the modern kinetic theory of matter. Perhaps the chapters just referred to, on properties of matter, constitute the most thoroughly successful portion of the book. We cannot call to mind any book in which an account of these subjects so good, and in itself so complete, can be found. The remaining chapters—with the exception of the last two, which are devoted to the electromagnetic theory of light and "the ether"—treat in detail of sound, light, heat, electricity, and magnetism. It is in the last-named portion of the book that students will feel a want of fuller and more complete treatment. The subject of heat in particular will be felt by many to be unduly compressed, and the same must be said of parts at least of electrodynamics and electromagnetism.

A book such as we have described, covering so wide a field, and brought into the narrow limits of 500 small octavo pages, must obviously, if it be well arranged and well written, be an important contribution to our scientific literature. We have no hesitation in giving it high commendation. There is, perhaps, not much that is absolutely novel in the treatment of the subjects, or in the matter, but that is hardly to be expected in a manual of this kind: the novelty is rather to be seen in the idea of the production of such a book.

While thus giving to the author warm praise and congratulation, we cannot avoid noticing serious faults both of commission and omission. First it seems simply deplorable to drag quaternion notions and notation into an elementary book of this kind, unless it be to show how ridiculous the riders of the quaternion hobby can at times become. The explanations and definitions at the commencement of chapter v. will be nothing to the majority of learners and teachers but a mass of confusion thrown over one of the simplest and most important of subjects. To prove by quaternions the formula $S = VT$ (space described in a given time with constant velocity), which needs only a knowledge of the multiplication table; or the formula $x = \frac{1}{2}gt^2$ for falling bodies, which can be explained by common-sense (but not by quaternions) to a boy of twelve in half an hour, is simply inexcusable. Wherever quaternions are introduced in this book we find an easy matter made difficult—if not, as in the case of simple harmonic motion, absolutely unintelligible. Unfortunately, Dr. Peddie is not the first writer who has contrived, by means of quaternions, to make a subject unnecessarily difficult and repulsive.

But by far the most serious defect of this book, and it is one which will greatly mar both its usefulness as a text-book and also its popularity as a somewhat elementary work for reading and consultation, arises from the failure of its author to catch, even in a remote degree, the spirit which has animated and directed the whole of the best experimenting in physics for the last twenty-five or thirty years. *Et ignem regunt numeri* is the motto of Fourier's great work; and a realization of the fact that numbers (not merely numerical ratios) must be sought for as the crown of physical laws is that which has given pre-eminent value to the labours of experimenters during the last half-century, and has forced workers in this great field into precision and definiteness. The example set by Gauss and Weber, Joule and Thomson, and by the British Association Committee on Standards of Electrical Resistance appointed in 1861, has revolutionized ideas as to what is the ultimate object of experimenting in physics; and we can no longer be satisfied with knowledge as to almost any physical phenomenon until we are able to apply to the phenomenon and to our laws the searching test of arithmetical calculation in absolute numbers.

Unfortunately, in the book before us there is no recognition of these necessary conditions for completeness of knowledge, and very little recognition of recent investigations of the kind here indicated. The failure will be felt most seriously in the important subjects of heat, magnetism, and electricity.

In electricity there is not to be found the resistance, whether in ohms or in C.G.S. units, of any wire of any material! There are pages of algebra on dimensions of units, to puzzle the unfortunate learner, but nowhere can he find what an ohm, or ampere, or volt is: unless, "$ohm = 10^9$ *C.G.S.*" can be taken as a definition, when the meaning of a C.G.S. unit is not explained. Faraday's laws of electrolysis, got fifty years ago, are stated; but the determinations of Lord Rayleigh and Kohlrausch of the amount of silver deposited by an ampere current in a second are not even referred to. Tait's thermo-electric curves, and some forms of galvanic cells are described; but how to find the electromotive force of any one combination in volts is not indicated. We must not multiply instances. It would be only wearisome. Magnetism, electro-dynamics, are treated in precisely the same way; and the student would find it impossible to calculate from data in this book how much heat is conducted across a stone slab in an hour under given conditions, or how much heat is lost from the surface of a sooted globe in a minute, though there is a great deal of exposition of laws of heat exchanges, and of the algebra pertaining thereto. Diffusion of matter is another subject which suffers from defective treatment in a similar way. The word "diffusivity," introduced by Thomson, is correctly defined on p. 131; but ten lines lower down the definition is departed from, and a column of relative numbers is substituted for the now fairly known absolute diffusivities. A very thorough change of all these parts of the book ought to be made in a reprint or new edition, in order to make the work conformable to modern knowledge and requirements.

It would be ungracious to point out too many minor faults in a first edition; but a few must be mentioned. Faraday seems to have been forgotten in connection with liquefaction of gases! and Melloni, though not perhaps absolutely trustworthy, surely deserved to have his name mentioned in connection with radiation of heat. Mayer's name is not mentioned; and, whatever Dr. Peddie may think on the subject of the celebrated controversy, no one will agree with him that the name should be *omitted*. We cannot help feeling that there is too much local colouring about many parts of the book. A book of this kind is sadly marred by want of proportionate distribution of treatment; even the occupation of space with minute treatment of a favourite subject becomes an injustice with regard to those subjects which are unduly curtailed for want of more space. We trust it will not hurt the feelings of anyone if we remark that the book should be a little more cosmopolitan, and a good deal less Scotch.

On p. 337, there is a mistake which will bear comparison with Lord Brougham's celebrated idea that people carry weights on their heads to have them farther from the centre of the earth, and therefore less attracted. The formation of ice in "very hot" countries on shallow pools is compared with Faraday's experiment of freezing mercury in a white-hot crucible. It is radiation, not forced evaporation, which is the cause of the phenomenon referred to.

We regret, also, that Dr. Peddie has thought it advisable to follow the example of Maxwell and others in changing Andrews's diagram right for left. There is no reason for doing so. The diagram was much better as Andrews originally gave it; and it would be better also without the dotted line said to separate the region in which liquid and gas can exist together from the regions in which the substance is entirely liquid or entirely gaseous. The former is a region concerning which there has been much speculation of an unprofitable sort. The elementary student need not be troubled with it, and it cannot be explained to him in a single sentence.

On p. 95 there is a diagram of a cord being pulled through a tube. Perhaps it cannot be asserted that the diagram is absolutely wrong, because the cord is said in the text to be perfectly flexible. But the cord, passing round corners which look as if they were sharp angles, is so strikingly unlike anything which can be realized (and the results explained in this section can to a great extent be experimentally realized), that the diagram becomes at least misleading. If the corners are sharp by intention, then the diagram *is* absolutely wrong.

In spite of the faults and defects we have been obliged to notice, this book is, as we have said, an admirable attempt at a very worthy object, and with some remodelling it can be made into an excellent text-book. We wish it all success, feeling well satisfied that it meets a decided want.

OUR BOOK SHELF.

The Dietetic Value of Bread. By John Goodfellow, F.R.M.S. (London: Macmillan and Co.)

THIS book is another addition to the useful series of "Manuals for Students," published by Messrs. Macmillan and Co. The author states in his preface that the object of the work is twofold. First, to lay before the general public an account of the various kinds of bread, by which their merits may be judged; and, secondly, to afford technical information to students and others on the important subject of the true value of bread as a food. These objects have in every way been fulfilled. No one is more qualified to write such a book than Mr. Goodfellow, who by his previous writings has shown such a grasp of the subject with which he has to deal.

The first section of the volume is concerned with "Food, Diet, and Digestion." This is a very difficult matter to treat in a popular manner. It involves some of the most complicated problems of physiology. The author, however, has not shirked his task; anyone, however ignorant he may formerly have been on the processes by which food matters are rendered suitable for absorption and after-use by the human organism, if he reads through these pages carefully, cannot but help gaining much knowledge on the functions of the stomach and intestinal canal, and of the waste and work of the body.

The nature of the digestive fluids is not, of course, considered with the minuteness of detail necessary for a medical examination, but enough is said to render the following sections perfectly intelligible, although they are treated in a scientific manner.

"White Bread" is first considered. An introductory chapter is given describing the structure of the wheat grain, and the changes which flour undergoes when exposed to heat and the process of fermentation. Not only are the chemical and physiological properties of bread considered, but economical principles are gone into, and it is shown "that bread is one of the cheapest foods, not only with regard to the actual weight of nourishment obtained, but also with regard to the variety of the nutrient constituents; and the purchaser who expends his modest 2½*d.* in a 2-lb. loaf may rest assured that he could not spend his money to better advantage."

We further learn, however, that white bread is not a perfect food; those who partake of it should take care to supplement it largely with other foods, in order to make up for the lack of calcareous matter. On no account should it form part of the diet of children unless supplemented by milk or other foods rich in lime and phosphates.

Turning to "Whole-meal Bread," full descriptions are given of its composition, amount and nature of the salts present and their solubility; its digestibility, the waste present, and the action of bran on the intestine; its flavour, satiety, and dryness; and its effects on infants and children.

The ordinary whole-meal bread is not a desirable food, and far inferior to good white bread as regards the weight of actual nourishment and the thoroughness of the digestion. Its ingestion is often followed by diarrhœa, and the action of the bran increases the waste of food.

After a short consideration of some special forms of bread, such as "aërated," "bran," "rye" bread, &c., Mr. Goodfellow proceeds to speak of Meaby's Triticumina bread, of which he has a very high opinion, and believes that it is as near a perfect food as such a bread can be, and deserves the universal commendation which has been accorded to it by the medical and analytical world. "Germ," "diastase," "gluten" bread, &c., are then described, and the book finishes with short chapters on the diseases of bread and its medicinal properties.

To all who are interested in this subject, or wish to extend their knowledge of "the staff of life," we heartily recommend this volume.

Graduated Mathematical Exercises. Second Series. By A. T. Richardson, M.A. (London: Macmillan and Co., 1892.)

ON a previous occasion we have referred to the first series of exercises by Mr. Richardson. In these he led the student through a set of graduated examples, commencing with arithmetic and reaching those on cube root, compound interest, and quadratic equations.

In the present series, which is intended to be a continuation of the first, the relatively higher flights of mathematics have been dealt with. The problems have been arranged on the same lines, the more difficult of them being reached as advance is made, and include those on algebra, logarithms, trigonometry, mechanics, and analytical geometry.

An idea of the range over which each subject spreads can be gathered from the fact that all the problems will about suffice to cover such examinations as those of the Oxford and Cambridge Locals, and Army and Navy, allowing a small margin of safety.

Great care seems to have been taken to insure accuracy, every example having been worked out at least twice. For class work these examples will be found handy and a great saving of time, while for use at home the book should be widely employed.

Bibliothek des Professors der Zoologie und vergl. Anatomie, Dr. Ludwig von Graff, in Graz. (Leipzig: Wilhelm Engelmann, 1892.)

PROF. VON GRAFF is the lucky owner of a fine scientific library, which was formed mainly by Carl Theodor von Siebold, his father, and his grandfather, all of whom were professors. This library came into the possession of Prof. von Graff in 1882, and as it was too large for the modest dimensions of a German professor's house, he exchanged many books relating to practical medicine for zoological monographs and periodicals. At Graz the library is freely used by his assistants, pupils, and colleagues, and it is mainly for their benefit that the present catalogue has been issued. It consists of 337 closely printed pages, and is a compilation of considerable value, not only because it gives lists of authors and their works, but because of the admirable way in which the lists are arranged. The contents of the library are grouped under four headings—periodicals, auxiliary books (including works on University systems, bibliographical writings, dictionaries, &c.), *zoologia generalis,* and *zoologia specialis.*

The Canadian Guide-book. By Charles G. D. Roberts. (London: William Heinemann, 1892.)

TOURISTS and sportsmen in Canada ought to be very much obliged to Mr. Roberts for having provided them with this excellent Guide-book. The method he has adopted is that of Baedeker's Hand-books, and the result is in every way worthy of the models he has chosen. The work includes full descriptions of routes, cities, points of interest, summer resorts, fishing places, &c., in Eastern Ontario, the Muskoka district, the St. Lawrence region, the Lake St. John country, the maritime provinces, Prince Edward Island, and Newfoundland. In an appendix are given fish and game laws, and official lists of trout and salmon rivers and their lessees. The author generally compresses his information into as small a space as possible, but in dealing with the more interesting Canadian scenes has sought to make his descriptions lively and attractive. The volume is prettily printed, and is well supplied with maps and illustrations.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Question in Physics.

CAN there be a crowding of the particles of a gas to a much smaller compass without its being markedly heated? Can a gas expand without being cooled? It is probable that nearly every physicist will give negative answers to these questions, and yet the fact that such conditions may occur sometimes seems well established. The present writer, in 1889, attempted to determine the actual heating of air when compressed by a pump connected with the cylinder by a long tube, and found that the temperature was raised about 4° F. for a compression of 10 inches above atmospheric pressure. In like manner, on expanding this compressed air into the free atmosphere, it was found that the cooling was about 4°. These results were published in *Science*, vol. xv. p. 387, and were strongly combated by Prof. Ferrel and Prof. Marvin. Prof. Ferrel advanced, as applicable in this case, the well-known thermodynamic formula for the computation of the heat developed in a gas when compressed, as follows:—

$$\frac{t}{t'} = \left(\frac{p}{p'}\right)^{\cdot 291}$$

in which t and t' are the absolute temperatures corresponding to the pressures p and p'. Sir Wm. Thomson has given this formula in slightly different form, and with a larger exponent (see "Encyclopædia Britannica," vol. vii. p. 814). Prof. Ferrel found that, under the experimental conditions above, the heating should have been 43°, and the cooling 45°? (38°) (see *American Meteorological Journal*, vol. xii. pp. 339 and 340).

It seems very evident, however, that this formula can be used only when all the heat due to the work of compression is concentrated in the compressed air, and conversely when the air expands against an external resistance. An experiment by Joule will serve to elucidate this point. He determined the mechanical equivalent of heat by immersing the cylinder into which the air was to be compressed and the compressing pump in the same water-bath, and then determining the amount of compression and the total heat developed. This enables us to advance the proposition: *If air when compressed is to be raised to the temperature indicated by theory*, it is very *essential that all the heat developed in the work of compression should enter the air*. This seems self-evident; nevertheless, nearly all the errors that have entered the various discussions of this question have arisen from a neglect of this very obvious consideration.

In Joule's experiment let us suppose that the compressing pump had been in one bath, and the cylinder into which the air was compressed in another. Under these conditions, if no heat were lost, the first bath would have received very much the greater amount of heat. Now, if the compressed air in passing from the pump to the cylinder became cooled to the outside temperature, it is evident that all the heat due to the work of compression would have been disposed of outside the cylinder, and would not have been available for raising the temperature of the compressed air.

Instead of connecting the pump directly with the cylinder, let us take two cylinders of the same size, and connected by a tube. Compress the air in the first cylinder (A), to three atmospheres, the air in the other (B) being at atmospheric pressure. If we cool the air in A to the outside temperature, and then open the connection with B, the compressed air will rush from A to B, and an equilibrum will be established very quickly, the pressure in each cylinder being at two atmospheres. The air in A will be slightly chilled because of the work of imparting a certain velocity to the particles entering B, and the air in B will be slightly warmed from the impact of the particles rushing from A, but there will be no heating due to the work of an external force making the compression.

Instead of allowing the air in A to rush into B, suppose we open communication with the outside air. The resistance to the rush of air will be much less than before, and the chilling in A, due to the work of imparting a certain velocity to the air, would be slightly greater than in the previous case, but it is obvious that this will be vastly less than that given by the formula. We may say, then, that the conditions suggested by the questions above may be very easily brought about.

The compressed air in a cylinder has a potential energy or capacity to do work, and this energy may be transmitted to another cylinder having air at atmospheric pressure without loss, and plainly without imparting or losing any heat. We might compare it to the head of water in a pond. This water has a certain capacity to do work depending upon its head. We may enlarge the pond somewhat, and the capacity for doing work will remain almost unchanged. The extremely important bearing of these views upon problems in meteorology is very apparent. The convection theory of storms demands a cooling from the work of expansion in an ascending column of moist warm air; it would appear, however, that the cooling must be vastly less than has generally been considered probable.

H. A. HAZEN.

Aurora.

PERHAPS it may interest some of your readers to see a short abstract of the observations of aurora made here during the last months, this winter having been by far the richest in well-developed northern lights since the winter 1870–71. Beginning with the magnificent display of February 13, which lasted almost the whole night, sometimes with vivid red and green tints (it was first noted at 6h. 45m., and faded away in the moonlight between 15h. and 16h. astronomical time), and whose beams converged several times from a large part of the horizon towards the magnetic zenith (formation of corona was noted at 7h. 2m., 10h., and 13h.), we have had aurora on February 14, 15, 24, 25, March 1 (at 7h. high arch, with the highest part through α and β Cephei, 7h. 55m. corona, between 8h. and 10h. pulsating and flashing light, sometimes with apparently screw-formed motion), March 2, 3, 6 (at 10h. curtains and corona, yellow-green colours), March 24, 25, 26, 27, April 23, 24 (at 10h. 10m. curtains, yellow-green) April 25 (strong light visible through small openings in cumulo-stratus in the north). The last display was on May 1, with corona at 9h. 40m., after 10h. flashes, curtains, and beams, at 13h. beams. About 11h. there was a peculiar downward motion of reddish light near the north horizon.

The magnetic disturbances of February 13 were also the greatest we have had for some years. The magnetometers, of the Gaussian construction, are generally observed at 2h. and 21h., but on February 13 observations were made every hour from 11 p.m., in correspondence with Bosekop in Finmarken, where the German observers, MM. Brendel and Baschin, were taking magnetical observations and photographs of the aurora during February and part of January. In Christiania the perturbations were comparatively small in declination (westerly maximum 12° 35′ noted at 12h. 10m., minimum 11° 42′ at 15h. 18m., but neither of them absolute, the observations not being continuous); but the horizontal intensity, which had already begun to increase a little at 21h., February 12, varied by more than 0·03 C.G.S. units, a maximum of 0·171 having been noted at 2h. 30m., and a minimum of about 0·140 from 12h. 0m. to 13h. 20m.; as the mirror of the magnet was in both cases outside the scale, the values could only be roughly measured. At 16h. 0m. the bifilar had returned to the small end of the scale, but a nearly constant value of the horizontal intensity was only attained after 5h., February 14. The inclination had a maximum of 73° 18′ at 13h. 10m., from which it gradually diminished, with some fluctuations, towards the normal value, about 71° 0′.

With reference to Mr. Backhouse's observation of nacreous clouds in the morning of January 30 (Nature, xlv. p. 365), I may add that the same beautiful but as yet mysterious phenomenon was seen here January 30 and 31, both days in the south-west after sunset. Since the display of December 1885, mentioned by Mr. Backhouse, it has been seen here every year, except 1888, mostly for a day or two in January or February.

H. Geelmuyden.

University Observatory, Christiania, May 3.

Wave-Propagation of Magnetism.

In an interesting article in last month's *Philosophical Magazine*, Mr. Trowbridge has given an account of some experiments made by him with the view of examining for any indication of a definite rate of propagation in the magnetization of iron. In these experiments no indication was observed.

It seems to me, however, that nothing of this sort is likely to be observed where the magnetizing force is as great as that used by Mr. Trowbridge, and that there are two classes of disturbances to be carefully distinguished. For example, in Prof. Ewing's well-known magnetic model, something which looks very like a definite rate is to be seen in the case of a disturbance not sufficiently large to cause toppling over of the "molecule magnets"; that is to say, to cause the little magnets to pass through their positions of unstable equilibrium. On the other hand, with a larger disturbance the phenomenon visibly partakes of a different character. Here, throughout the medium, there are to be seen at irregular moments what may be considered as cases of precipitation of energy, owing to the occurrence of these positions of unstable equilibrium.

These two stages should be carefully distinguished, for an essential in wave-propagation as opposed to a rate of precipitation of energy (such as a rate of ignition, &c.) is obviously that the medium should not be permanently altered.

In some experiments made by me, very much smaller alternating currents than those used by Mr. Trowbridge were employed. But the occurrence of spurious effects, simulating to a remarkable degree the interference nodes looked for, must have effectually obscured in my experiments the true phenomenon, supposing its existence. So that, considering the conditions of both our experiments, I still think the subject requires further investigation before coming to a decision in the matter. Indeed, when larger currents are used, no indication is to be found of even these spurious effects.

In Prof. Ewing's model, when the magnets point on the whole the same way (representing a high state of magnetization), the rate of propagation of a small disturbance affords a more definite problem. Tried experimentally, this latter case might afford more satisfactory results. Fred. T. Trouton.

Correction in "Island Life."

In Dr. Merriam's recently published paper on "The Geographical Distribution of Life in North America," an important, and to me almost inexplicable error in my work "Island Life" is pointed out. It occurs at page 41 in the first edition, and is unfortunately repeated at the same page in the recently published new edition, and consists chiefly in stating that the moles (Talpidæ) are almost confined to the Palæarctic region. But a little further on in the same work (page 48 of first edition, and page 49 of second edition) it is correctly stated that there are three peculiar genera of moles in North America, and the same statement is made at page 115, and again at page 190 of vol. ii. of my "Geographical Distribution of Animals." At page 182 of vol. i. of the latter work, however, the error first appears, and it is this erroneous passage that has remained unnoticed till now, and was unfortunately repeated in "Island Life." In the same paragraph an error of a similar kind also occurs as to the distribution of the lynxes. To correct these errors pages 41 and 42 of the new edition of "Island Life" are being reprinted, and will be sent to all who possess the volume if they will forward a stamped and directed envelope to the publishers.

Alfred R. Wallace.

THE INTERNATIONAL CONFERENCE ON CHEMICAL NOMENCLATURE.

At the meeting of the International Chemical Congress, held in Paris in the summer of 1889, a special Section was appointed to consider the unification of chemical nomenclature, and, after discussing a variety of propositions, some of which were adopted, it was decided to form an International Commission for the further study of the subject.[1]

The members resident in Paris, having been constituted a permanent committee of the Commission, have devoted an immense amount of time and care to the preparation of a scheme, and it was to discuss their report[2] that we met at Geneva on Easter Monday last. The French Committee had issued invitations, not only to members of the Commission, but also to many other prominent chemists, so that the meeting was a thoroughly representative one. It is worth mentioning, as an illustration of the sympathetic treatment accorded by public bodies in France to men of science, that the Paris-Lyons-Marseilles Railway Company granted a reduction of one-half on the fare over their line to members of the Congress.

Very happily, the local committee had arranged that all might stay at the one hotel—the Métropole—and it was here that we first met in friendly union on the Monday evening.[3] The next morning the Congress assembled at the Hôtel de Ville, M. Richard, the Cantonal Minister of Education, being in the chair. After an admirable address of welcome from this gentleman, who appeared to thoroughly appreciate the importance of the object in view, on the motion of Prof. Cannizzaro it was wisely decided not to follow the complimentary, but somewhat unbusinesslike, Continental practice so frequently adopted, of appointing a different chairman each day, but to have only one. M. Friedel, who had taken the chair at all the numerous meetings of the Paris Committee, having been chosen by acclamation President of the Conference, formal business was at once entered into, and, after the necessary interval for lunch, the sitting was resumed in the afternoon. We met in like manner on the two following days, and the final sitting took place on the Friday morning, but many had left before this. On Tuesday evening, by invitation of the local committee, we visited the theatre, a very beautiful building. On the Wednesday evening, we were entertained by them at a dinner at the Hôtel Métropole, on which occasion a very striking speech was delivered by Prof. von Baeyer, who, after pointing out that experimental chemistry had been carried, early in the century, into Germany from France by Liebig, who was tutored by Gay-Lussac, proceeded to say that, although the science had now undoubtedly reached its highest development in Germany, it was more than probable that, in the future, circumstances would arise which would lead to some other nation—France, Russia, Italy, or England—coming to the fore. On this occasion, on the motion of M. Le Bel, it was unanimously decided to appoint M. Marignac Honorary President of the Congress, and a letter to him expressing our regret that ill-health prevented his taking part in its work was at once signed by all present. We were indebted in many other ways to the local committee, and there is no doubt that the success of the meeting was in large measure due to the forethought and hospitable care exercised by them on our behalf; absolute amity prevailed throughout, and it was clear that all were bent on co-operating to secure the carrying out to a successful issue of a very difficult but most important work. The great advantage to be derived from the personal intercourse which such meetings promote was soon apparent: gradually, the doubts which many entertained as to the possibility of devising a practical rational scheme of nomenclature were dispersed, and ere many hours had elapsed the sympathies of all present were enlisted on behalf of the work; thus a mission has been sent forth which will explain the enterprise to chemists generally.

---

[1] The following chemists eventually consented to serve on the Commission:—MM. Béhal, Berthelot, Bouveault, Combes, Fauconnier, Friedel, Gautier, Grimaux, Jungfleisch, Schützenberger (all representing France), Graebe (Switzerland), Alexejeff and Beilstein (Russia), von Baeyer and Nölting (Germany), Lieben (Austria), Paterno (Italy), Franchimont (Holland), Armstrong (England), Istrati (Roumania), Calderon (Spain), Cleve (Sweden), Boukowski-Bey (Turkey), Ira Remsen (United States), and Mourgues (Chili).

[2] This report had been prepared by the following:—MM. Friedel (President), Béhal, Bouveault, Combes, Fauconnier, Gautier, and Grimaux.

[3] The following is the official list of those who took part in the Conference:—MM. H. E. Armstrong, professeur à la Central Institution, Londres, secrétaire de la Chemical Society; A. Arnaud, professeur au Muséum, à Paris; Adolphe von Baeyer, professeur à l'Université de Munich; Barbier, professeur à la Faculté des sciences de Lyon; Aug. Béhal, professeur à l'École supérieure de pharmacie de Paris; Louis Bouveault, docteur ès sciences, Paris; Stanislas Cannizzaro, professeur à l'Université de Rome; Paul Cazeneuve, professeur à la Faculté de médecine de Lyon; Alphonse Combes, docteur ès sciences, Paris; Alphonse Cosso, directeur de la Station expérimentale d'agriculture, à Turin; Maurice De Lacre, professeur à l'Université de Gand; Michel Fileti, professeur à l'Université de Turin; Emile Fischer, professeur à l'Université de Würzbourg; A.-P.-N. Franchimont, professeur à l'Université de Leide; Charles Friedel, membre de l'Institut, professeur à la Sorbonne, Paris; Dr. J. H. Gladstone, F.R.S., Londres; Carl Graebe, professeur à l'Université de Genève; Philippe-Auguste Guye, professeur à l'Université de Genève; Istrati, professeur à l'Université de Bucarest; Albert Haller, professeur à la Faculté des sciences de Nancy; Maurice Hanriot, professeur agrégé à la Faculté de médecine, Paris; A.-R. Hantsch, professeur à l'École polytechnique de Zurich; Achille Le Bel, docteur ès sciences, à Paris; A. Lieben, professeur à l'Université de Vienne; Léon Maquenne, docteur ès sciences, aide-naturaliste au Muséum, Paris: von Meyer, professeur à l'Université de Leipzig; Denis Monnier, professeur à l'Université de Genève; R. Nietzki, professeur à l'Université de Bâle; Emilio Noelting, directeur de l'École de chimie de Mulhouse; Emmanuel Paterno, professeur à l'Université de Palerme; Amé Pictet, privat-docent à l'Université de Genève; William Ramsay, F.R.S., professeur à l'Université de Londres; Zdenko-H. Skraup, professeur à l'Université de Graz; Ferdinand Tiemann, professeur à l'Université de Berlin.

Le Comité local d'organisation se composait de:—MM. Emile Ador, H.-W. de Blonay, Alex. Claparède, Professeur C. Graebe, Professeur Ph.-A. Guye, Alex. Le Royer, Professeur Denis Monnier, Amé Pictet, Fréd. Reverdin, Professeur Albert Rilliet, Edouard Sarasin.

The resolutions passed at the meetings are appended to this article. These, I think, are in no way to be taken as in all respects final, but they will serve to prepare the way and to indicate the lines on which the work is to be carried out. The position in which we found ourselves placed, in fact, was not one which justified our arriving at decisions which could fairly be regarded as binding. The report of the French Committee was placed in our hands only on the morning of the first meeting, and it was impossible to master its contents at so short a notice, and still less to criticize and test the application of its recommendations in detail. That the scheme would serve but as the basis for discussion was soon evident, when at the very outset a system of nomenclature for the hydrocarbons was adopted very different and far more significant than that recommended in the report; and numerous other departures from its recommendations were carried in the course of the proceedings. Again, some of the most active members of the Congress had confessedly paid attention only to special groups of compounds, and had not tested the application of proposals which they strenuously advocated to compounds of other groups; but as a nomenclature admirably adapted to one class may be open to all sorts of objections when applied to another, the general bearing of recommendations made with reference to special groups will have to be fully considered before they can be finally adopted. The resolutions relating to fatty acids (Nos. 18, 19) are of this kind, and their adoption was warmly opposed by an important minority on the ground that, however well they might be adapted to acids pure and simple derived from open-chain hydrocarbons, their application to acids derived from closed-chain hydrocarbons and acids containing other radicles in addition to carboxyl was beset with difficulty. In order to name an acid in accordance with this resolution, the formula of the corresponding hydrocarbon must be constructed from that of the acid by changing carboxyl into methyl; for example, citric acid, $CH_2(CO_2H).C(OH)(COOH).CH_2(COOH)$, would have to be regarded as a derivative of methylpentane, and would be named methylpentanoltrioic acid, numerals being added to indicate the positions of the hydroxyl and carboxyl groups; in like manner, mellithic acid, $C_6(COOH)_6$, would be named hexamethylbenzenehexoic acid, although no methyl is present in it. The mental effort involved in visualizing the formulæ from such names as these would appear to be far greater than if they were respectively named propanoltricarboxylic acid and benzenehexacarboxylic acid, or simply propanoltri-acid and benzenehexacid, the use of the term *acid* being understood to imply the presence of carboxyl. A decision on points such as these can only be arrived at after careful study of the general effect of such a proposal, and there was no time for such a comparison during the brief debate possible at a Conference. In some cases, there can be no doubt that the full force of objections raised to proposals in favour of which a majority subsequently voted was not felt, owing to the difficulty which necessarily arises at an international Conference if the language used be not equally familiar to all present, and consequently full expression cannot be given by all to their views. Moreover, although it is easy to criticize destructively even at short notice, constructive criticism under such circumstances is very difficult; consequently a proposal may be accepted even in face of serious objections to its adoption simply because nothing better can be suggested at the time. An instructive case of the kind arose on discussing thio-compounds. The proposals in the French report were not regarded as altogether satisfactory, and an amendment was suggested and carried which to many appeared most undesirable: the next morning, when the time came to confirm the resolutions arrived at on the previous day, the discussion was reopened, and a slight modification of the original proposal was suggested, which was recognized to be an improvement, and the objectionable resolution was rescinded. Clearly at such meetings much must depend on the right expression being found by happy inspiration at the right moment.

The one resolution which covers all others and which defines the nature of the task to be undertaken is the first. Whatever name we may choose to apply to a substance colloquially, it is clearly an absolute necessity of the times that every compound should bear a *systematic* name of such a character that it can be at once translated into the corresponding formula; and that, *vice versâ*, a name corresponding to any particular formula may be devised which we may count on finding in the *official* register, if the compound thought of have been described. The value of such a systematic nomenclature to original workers as well as to students cannot be over-estimated, and few who are qualified to take part in such a work will grudge the time they may spend on it. There was considerable difference of opinion at the meeting as to whether a systematic nomenclature should be devised merely for the purpose of an official register, or whether the object aimed at should be a system of wider application: the majority, I believe, came to the conclusion that it should certainly subserve the one, but if possible both purposes. There can be little doubt, however, that the future student will cut the knot by declining to burden his memory with a double vocabulary in the case of all but the commonest substances, and that therefore there is but one course open to us (cf. Res. 26).

Although sufficiently conservative to retain methane, ethane, propane, and butane, the Congress decided not to adopt the proposal to continue the use of the names formic, acetic, propionic, and butyric for the first four acids of the acetic series, which was advocated by a substantial minority on the ground that their retention would facilitate the change from the old to the proposed new system. This is one of the questions demanding careful consideration. Many will, no doubt, prefer to retain old unsystematic names as far as possible, but it is easy to see that the desire to avoid change may carry us too far in this direction; it will undoubtedly be very inconvenient to the present generation of chemists to abandon familiar and cherished names, but nevertheless it may be a wise course to boldly face the difficulty, rather than inflict on coming generations a partially illogical and unsystematic nomenclature. The argument that the present familiar names may still be used colloquially is, as I have already said, scarcely a justification of the dismissal of such names from the official nomenclature, as our successors may be expected to object more and more decidedly to a multiplex system as chemical science progresses, and to insist on the adoption of the official as the sole system: the extent to which familiar trivial names shall be retained in the official system is therefore a matter of great importance.

As one aim and object must be to devise a system which is significant and logical throughout, no considerations must be allowed to prevail which will defeat this, and it will not suffice to quote present usage in support of illogical proposals; but this has been done. Thus the Congress decided (Res. 46) to name compounds of the type $R'.N_2.R'$ *azo*-compounds, while retaining the name *diazo*-chloride for $C_6H_5.N_2Cl$. It matters not to us that the manufacturers have chosen to call the colours derived from *di*azo-compounds azo-dyes; if substances such as $(C_6H_5)_2S$ are termed *thio*, and compounds such as $(C_6H_5)_2S_2$ *di*thio-compounds (Res. 43), we are bound to be consistent, and apply the significant term diazo- to substances containing two nitrogen atoms. Resolution 46 ought therefore to be in part rescinded. I call attention to this case as an illustration of the tendency to break away from uniformity in favour of what may fairly be termed popular prejudice, which will require to be most carefully guarded against if the various sections of our system are to harmonize.

It will be gratifying to English chemists that the principle advocated for many years past by our Chemical Society, and enforced in its "Instructions to Abstractors"—that particular terminations should be regarded as indicative of particular functions, and should therefore be restricted to particular classes of compounds—has been legalized and extended by the Congress. This is a step of great importance, as we may expect that it will affect even trivial names, and that in future names will be given to new substances which will to a certain extent afford a clue to their nature; the hopeless confusion which now reigns supreme in the pages of the *Berichte*, for example, owing to the disregard of this principle by our German colleagues—who have hitherto been, as a rule, almost uniformly neglectful in matters of nomenclature—will, it may be hoped, ere long give way to more orderly treatment.

But the importance of applying this principle logically was not fully grasped even at the Congress, inasmuch as it was decided to affix the termination *ine* to acetylenic hydrocarbons, notwithstanding that this termination is admittedly indicative of basic properties. If, however, a suitable suffix ending in *ene* could be thought of, there would probably be little difficulty in securing its acceptance, in which case unsaturated hydrocarbons generally would have names ending in *ene*, and saturated hydrocarbons names ending in *ane*, and these terminations could be reserved exclusively for hydrocarbons.

It will be obvious from the foregoing remarks that although a solid foundation for our future system of nomenclature has been laid, much remains to be done before a mature design, perfect in all its details, can be presented for adoption. At the meeting the hope was expressed that a decision might be speedily taken, to enable Beilstein to utilize the proposals in the preparation of the third edition of his marvellous work; but it is clear that we are not yet so far advanced as to make this possible or even desirable, and it would be most unfortunate if Beilstein were at the present juncture to promulgate a system which is manifestly incomplete: nothing can be worse in such a case than to consent in haste, when it is evident that this would surely involve repentance at leisure.

Those of us who are interested in the work, and competent to advance it, must now test in detail the application of the proposals which have been provisionally adopted, and we must assist in contributing to the ultimate establishment of a system on the broad lines of policy laid down for our guidance at the Congress. As it is not improbable that in the future, owing to the extended use of our language, the major proportion of chemical students will speak English, it is essential that due attention be paid to the matter here in England, so that a system may be devised which we can make use of without difficulty.

HENRY E. ARMSTRONG.

Résolutions prises par le Congrès.

1. A côté des procédés habituels de nomenclature, il sera établi un nom *officiel* permettant de retrouver chaque corps sous une rubrique unique dans les tables et dictionnaires.

Le Congrès exprime le vœu que les auteurs prennent l'habitude de mentionner dans leurs mémoires, entre parenthèses, le nom officiel à côté du nom choisi par eux.

2. On décide de ne s'occuper, pour le moment, que de ce qui concerne les composés de constitution connue, et de remettre à plus tard la question des corps à constitution inconnue.

3. La désinence *ane* est adoptée pour tous les hydrocarbures saturés de la série grasse.

4. Les noms actuels des quatre premiers hydrocarbures saturés (*méthane*, *éthane*, *propane*, *butane*) sont conservés; on emploiera les noms dérivés des nombres grecs pour ceux qui ont plus de quatre atomes de carbone. Ces noms désigneront les hydrocarbures normaux.

5. Les hydrocarbures à chaîne arborescente sont regardés comme dérivés des hydrocarbures normaux, et on rapporte leur nom à la chaîne normale la plus longue qu'on puisse établir dans leur formule.

6. Le numérotage des chaînes latérales partira de l'atome de carbone terminal le plus rapproché d'une chaîne latérale; dans le cas où les chaînes latérales les plus voisines des extrémités seraient placées symétriquement, la plus simple décidera du choix.

7. Lorsqu'un résidu se substitue dans une chaîne latérale, on emploie *métho-*, *étho-*, etc., à la place de *méthyl-*, *éthyl-*, préfixes réservés pour le cas où la substitution se fait dans la chaîne principale.

8. Dans les hydrocarbures ayant une seule *double liaison*, on remplacera la terminaison *ane* de l'hydrocarbure saturé correspondant par la terminaison *ène* (ex. éthène); s'il y a deux doubles liaisons, on terminera en *diène* (ex. propadiène), s'il y en a trois, en *triène*, etc. Si cela est nécessaire, la place de la double liaison est indiquée par le numéro du premier atome de carbone sur lequel s'appuie cette double liaison.

9. Les noms des hydrocarbures à *triple liaison* se termineront pareillement en *ine*, *diine* et *triine* (ex. éthine pour acétylène. propine pour allylène, hexadiine pour dipropargyle).

10. Dans le cas où il y aurait simultanément des doubles et triples liaisons, on emploiera les désinences *énine*, *diénine*, etc.

11. En ce qui concerne les hydrocarbures saturés à chaîne fermée, ils prendront les noms des hydrocarbures saturés correspondants de la série grasse précédés du préfixe *cyclo* (ex. cyclohexane pour hexaméthylène).

12. Les atomes de carbone d'une chaîne latérale seront désignés par le même chiffre que l'atome de carbone auquel la chaîne est attachée. Ils porteront un indice qui indiquera leur rang dans la chaîne latérale en partant du point d'attache.

Dans le cas où deux chaînes seraient attachées au même atome de carbone, les indices de la plus simple d'entre elles seront accentués.

Le même mode de numérotage est adopté pour les chaînes latérales des chaînes fermées.

13. Les hydrocarbures non saturés seront numérotés comme les hydrocarbures saturés correspondants. Dans le cas d'ambiguïté ou d'absence de chaîne latérale, on placera le n° 1 au carbone terminal le plus rapproché de la liaison d'ordre le plus élevé.

14. Le numérotage des hydrocarbures est conservé pour tous leurs produits de substitution.

15. On nommera les alcools et les phénols du nom de l'hydrocarbure dont ils dérivent, terminé par le suffixe *ol* (ex. pentanol, penténol, etc.).

16. Quand on a affaire à des alcools ou à des phénols polyatomiques, on intercalera, entre le nom de l'hydrocarbure fondamental et le suffixe *ol*, une des particules *di*, *tri*, *tétra*, etc., suivant l'ordre de la polyatomicité (ex. propane-triol pour glycérine).

17. Le nom de *mercaptan* est abandonné, et cette fonction sera désignée par le suffixe *thiol* (ex. éthane-thiol).

18. Dans les acides de la série grasse, le carboxyle sera considéré comme faisant partie intégrante du squelette de carbone.

19. Le nom de tous les acides monobasiques de la série grasse est tiré de celui de l'hydrocarbure correspondant suivi du suffixe *oïque*.

On désignera les acides polybasiques par les terminaisons *dioïque*, *trioïque*, *tétroïque*, etc.

20. Les résidus monovalents des acides seront dénommés en transformant en *oyle* la terminaison *oïque* de l'acide.

21. Dans les acides monobasiques à chaîne normale saturée ou symétrique, le carbone du carboxyle porte le n° 1.

22. Les acides dans lesquels un ou plusieurs atomes de soufre remplacent autant d'atomes d'oxygéne du carboxyle seront désignés comme suit : le soufre simplement lié à un atome de carbone sera désigné par le suffixe *thiol* ; si la liaison est double, on emploiera le suffixe *thion*. Exemples :

$CH_3.CO.SH$ Acide éthane-thiolique.
$CH_3.CS.OH$ Acide éthane-thionique.
$CH_3.CS.SH$ Acide éthane-thionthiolique.

23. Le Congrès donne son adhésion à la proposition suivante sans émettre de vote définitif à ce sujet :

Les éthers-oxydes seront désignés par les noms des hydrocarbures qui les composent, reliés par le terme *-oxy-* (ex. pentane-oxy-éthane pour oxyde d'éthyle et d'amyle).

24. Les anhydrides d'acides conserveront leur mode actuel de désignation d'après le nom de leurs acides (ex. anhydride éthanoïque).

25. (12 *bis*). Dans le cas de deux chaînes latérales attachées au même atome de carbone, l'ordre dans lequel ces chaînes seront énoncées correspondra à leur ordre de complication.

26. Une discussion plus approfondie sur la nomenclature des composés à fonctions complexes est ajournée, et l'étude de cette question est renvoyée à la Commission internationale, pour qu'elle prépare sur ce point un projet qui sera présenté à un prochain Congrès ; la Commission cherchera à concilier les exigences de la nomenclature parlée avec celle d'une terminologie applicable aux dictionnaires.

27. On conservera les conventions habituelles pour les sels ou éthers composés.

28. Les lactones seront désignées par le mot *olide*, indiquant que c'est un anhydride interne d'alcool et d'acide. La position de la fonction alcoolique, par rapport au carboxyle de l'acide alcool d'où dérive la lactone, pourra être exprimée par les lettres grecques α, β, γ, δ, à côté du numérotage habituel des chaînes latérales :

$$\begin{array}{ccccccc} & & \mathrm{O} & \text{—} & \text{—} & \text{—} & \mathrm{CO}\\ & & | & & & & |\\ \mathrm{CH_3} & \text{—} & \mathrm{CH} & \text{—} & \mathrm{CH_2} & \text{—} & \mathrm{CH_2}\end{array}$$

1.4 pentanolide ou 1.4 γ pentanolide.

29. Les acides lactoniques dérivant d'acides bibasiques seront nommés comme les lactones dont ils dérivent, en ajoutant le suffixe *oïque*, caractéristique des acides.

30. La discussion sur les chaînes fermées est ajournée jusqu'au moment où la publication des idées de M. Armstrong, sur ce sujet, aura permis à la Commission internationale de les comparer avec les propositions de M. Bouveault.

31. Dans la série aromatique et tous les corps renfermant une chaîne fermée, toutes les chaînes latérales seront considérées comme des substituants.

32. Aldéhydes. Seront désignées par le suffixe *al* (méthanal, éthanal).

Aldéhydes sulfurées ; suffixe *thial*.

33. Acétones : suffixe *one* ($CH_3.CO.CH_2.CH_3$, butanone 2).

Diacétones, triacétones : suffixes *dione*, *trione*.

Acétones sulfurées : suffixe *thione*.

34. Quinones : Le suffixe *quinone* sera conservé pour les corps homologues de la quinone ordinaire.

Les corps ayant plusieurs fois le chaînon CO.CO seront des diquinones ou triquinones.

35. Ammoniaques composées : pas de changement (ex. éthylamine, éthène-diamine).

Les corps où le groupe bivalent —NH— ferme une chaîne formée de radicaux positifs seront appelés *imines* (ex. éthène-imine).

Phosphines, arsines, stibines, sulfines : la nomenclature en usage est conservée.

36. Hydroxylamine : ce nom est conservé.

37. Oximes : seront désignés en suivant les règles actuellement admises ; les corps *isonitrosés* seront nommés comme oximes.

(Ex. $CH(NOH).CH_2.CH_2CH_3$ 1 Butanoxime
$CH_3.CH_2.C(NOH).CH_3$ 2 Butanoxime.)

38. Amides : ce nom sera conservé (ex. Ethanamide

$NH_2.CO.CH_2.CH_2.CO.NH_2$ Butane-diamide
$COOH.CO.CH_2.CH_2.CO.NH_2$ Acide butanamidoïque).

Imides : seront conservées.

Amidoximes : ce nom sera conservé.

(Ex. $CH_3.C(NOH).NH_2$ Ethanamidoxime.)

Urée : le mot générique *urée* sera conservé, on l'emploiera comme suffixe pour les dérivés alcoylés de l'urée, tandis que les dérivés par substitution acide seront des *uréides*.

Les corps dérivant de deux molécules d'urée seront désignés par les suffixes *diurée*, *diuréide*. Les uréides acides prendront le nom d'*acides uréiques*. On rejettera les désinences *uramique* et *urique*.

39. Amidines : ce suffixe sera conservé.

(Ex. $CH_3.C.NH.NH_2$ Ethanamidine).

Pour les dérivés, le nom sera dédoublé, et l'on fera précéder du nom du groupe substituant, soit amino, soit amidine, suivant le cas.

(Ex. $CH_3.C(NC_2H_5).NH_2$ Ethanaminoéthylimidine.
$CH_3.C(NH).NHC_2H_5$ Ethanéthylamino-imidine.)

Guanidines : le mot générique *guanidine* est conservé, mais différentes guanidines seront nommées comme dérivés substitués de la diamidocarbo-imidine.

40. Bétaines : suffixe *taïne*.

(Ex.

$$\begin{array}{ccc}\mathrm{N(CH_3)_3} & \text{—} & \mathrm{O}\\ | & & |\\ \mathrm{CH_2} & \text{——} & \mathrm{CO}\end{array}$$

Ethanoyltriméthyltaïne.)

41. Nitriles : la question est laissée en suspens pour la série grasse. Pour la série aromatique, on adopte le préfixe *cyano* (comme nom de substituant).

42. Carbylamines : la nomenclature actuelle est conservée.

43. Sulfones : ce nom est conservé.

(Ex. $C_6H_5.SO_2.C_6H_5$ Benzène-sulfone-benzène.)

Sulfures : on les désignera en intercalant *thio* entre les noms des deux composés saturés (décision provisoire).

(Ex. $C_6H_5.S.C_6H_5$. Benzène-thio-benzène.)

Disulfures : seront désignés de même par *dithio*.

44. Ethers isocyaniques : suffixe *carbonimide*. Ex. Ethylcarbonimide désignera le cyanate d'éthyle de Wurtz ; on dira de même éthylthiocarbonimide pour le dérivé sulfuré correspondant.

Cyanates : ce nom est conservé aux vrais éthers qui, par saponification, donnent de l'acide cyanique ou ses produits directs d'hydratation. On remplacera le nom de sulfocyanate par celui de *thiocyanate*.

45. Corps nitrés : rien à changer à la nomenclature actuelle.

46. Corps azoïques : les dénominations *azo* et *diazo* seront conservées, mais le mode d'énonciation de ces composés sera modifié comme suit :

(Ex. $C_6H_5.N_2.Cl$ Chlorure de diazobenzène.
$C_6H_5.N_2.C_6H_5$ Benzène-azo-benzène.
$C_6H_5.N_2.C_6H_4.N_2.C_6H_5$ Benzène - azo - benzène - azo-benzène.)

THE GEOLOGY OF BARBADOS.[1]

THE oceanic series of Barbados forms a group of beds which is clearly marked off from the Scotland series below, and the coral limestone above. The oceanic deposits do not, however, appear everywhere as a continuous band between the two other formations, because the elevation of the island from oceanic depths was accompanied by a considerable amount of faulting, and tracts of the oceanic deposits were dropped down between blocks of the Scotland series. Although this faulting

---

[1] "The Geology of Barbados. Part II. The Oceanic Deposits." By A. J. Jukes Browne and J. B. Harrison. Abstract of paper printed in the Quarterly Journal of the Geological Society, May 1892.

interferes with the continuity of the oceanic deposits, it is abundantly clear from numerous sections that they rest unconformably upon the Scotland series, and are as distinct in respect of age as they are in respect of lithological composition, and a greater contrast in all respects can hardly be imagined than these two formations present.

The oceanic series is more than 300 feet thick, and is divisible into five portions, which, however, blend into one another. These are, in descending order—

(1) Grey siliceous mudstones, consisting chiefly of fine volcanic dust, with a few fragments of siliceous organisms.

(2) Very fine-grained argillaceous earths, often red or pink, but sometimes yellow or buff; these are analogous to modern oceanic "red clays."

(3) Pulverulent chalky marls and earths, being consolidated foraminiferal oozes passing down into calcareo-siliceous earth with Radiolaria; proportion of carbonate of lime, 80 to 44 per cent.

(4) Siliceous Radiolarian earth, consisting mainly of Radiolaria, with sponge spicules and Diatoms, and a small amount of fine calcareous matter.

(5) Calcareo-siliceous earths, with 25 to 40 per cent. of carbonate of lime passing down into purer chalky earth, with 60 to 80 per cent., which is in some places converted into limestone by the infiltration of calcite.

There is a considerable variation in the amount of chalky matter even on what appears to be the same horizon, and within short distances. The whole series is more calcareous in the northern than in the southern part of the island.

Interstratified layers of volcanic sand and dust occur at several horizons, some of them being light grey pumiceous and felspathic sand, and others a mixture of such material with Radiolarian earth stained brown by what seems to be petroleum.

With respect to organic remains, the calcareous earths have yielded *Foraminifera* in abundance, a preliminary examination of six samples by the late Dr. H. B. Brady resulting in the discovery of 81 species. The siliceous earths have furnished the specimen of *Cystechinus crassus* recently described by Mr. J. W. Gregory, and they abound in Radiolaria, as is very well known. Certain marls and limestones on Bissex Hill prove to consist mainly of *Globigerina*.

The bearing of these fossils is discussed with regard to (1) the age, (2) the conditions of depth, at which the deposits were formed. The age is Pliocene, or Pleistocene, while stratigraphical considerations make it most probable that they are of Pliocene date.

The depth of water indicated by the Foraminifera is from 500 to 1000 fathoms, according to Dr. Brady. The *Cystechinus* is considered by Mr. Gregory as strong evidence for a depth of over 1000 fathoms, and is quite consistent with a depth of over 2000; while the Radiolaria are, in Prof. Haeckel's opinion, most nearly allied to those which occur in the deepest parts of modern oceans, *i.e.* about 3000 fathoms.

The coloured clays are remarkable for the almost complete absence of carbonate of lime; they correspond in all essential points to those modern argillaceous oozes which occur at from 2500 to 3000 fathoms, and have little or no carbonate of lime.

The available evidence points to the conclusion that the depth of water varied from 1000 to 2500 fathoms, and there may have been two epochs at which it was over 2000 fathoms.

Radiolarian deposits have for some years been known to exist in Trinidad, and the authors, having obtained samples, are able to announce that these closely resemble the Barbadian earths in general aspect, in chemical composition, and in microscopical structure. Similar earths also appear to exist in Hayti.

Finally, they discuss the changes in physical geography which are indicated by the existence of these deposits, and their probable equivalent in part of the white limestone of Jamaica; and they infer that the whole Central American and Caribbean region was deeply submerged during the Pliocene period, and that during this time there was open and free communication between the Atlantic and Pacific Oceans. The separation of the two oceans, and the deflection of the Gulf Stream, were changes accomplished by the upheaval of which evidence was adduced in a former paper, and this upheaval is a comparatively recent event.

The minute structure of the rocks is described in reports presented by Mr. W. Hill and Miss C. A. Raisin; the former showing that the Barbados chalk is similar in all essential points to the Chalk of England.

EDUARD VON REGEL.

THE learned and genial Director of the St. Petersburg Botanic Garden, Dr. Eduard von Regel, died on April 27, in his seventy-seventh year. He was the son of a Gotha parson, and developed a taste for gardening while still quite young. During the hours that might have been given to play he was usually engaged at his favourite pursuit in his father's garden. After the usual course of education, he spent several years in various botanic gardens, and about 1842 he was appointed "Obergärtner" in the Botanic Garden at Zurich. Here, in conjunction with Dr. O. Heer, the celebrated palæontologist, one of whose daughters he subsequently married, he at once founded a Swiss journal for agriculture and horticulture, and was exceedingly active in promoting horticulture, both in writing and practically. In 1852 he founded the now well-known and still flourishing *Gartenflora*, which, however, he ceased to edit after 1885. He soon gained fame, and when the important post of Scientific Director of the St. Petersburg Botanic Garden became vacant in 1855, it was offered to and accepted by Regel, and held by him to the last. There he found a wide field for his energy and abilities: but although he accomplished much meritorious botanical work, Russia is far more indebted to him for the improvements he effected in horticulture generally than for his botany. At the time when he first went to St. Petersburg, gardening was at a very low ebb, and the vast strides that have since been made in this industry are very largely due to his untiring efforts. He wrote treatises, introduced superior varieties of fruits, vegetables, and flowers, and succeeded in gaining the influence and support of exalted persons for his projects both botanical and horticultural. It was mainly through his exertions, we believe, that the first flower-show was held in St. Petersburg. This was in 1858, and now such a thing is no uncommon event. He was also instrumental in getting botanists attached to the Russian exploring expeditions in Central and Eastern Asia, whereby the gardens and herbaria, not only of Russia, but of Europe, have been greatly enriched, and botanical science advanced. Regel himself elaborated many of the dried collections thus obtained, besides describing a large number of plants cultivated in the garden from seeds or bulbs sent thither by various travellers. One of the best of his numerous writings is a monograph of the genus *Allium*—"Alliorum adhuc cognitorum Monographia,"—the number of species described exceeding 250, including a large number previously undescribed, the fruits of the explorations in Asia. He was also joint author of an enumeration of the plants collected in Siberia by Semenoff, Radde, Stubendorff, and others. Although gradually declining in health during the last year or so, he continued to discharge the duties of his office; and although not so active with his pen as formerly, he contributed some descriptions of new plants to the *Gartenflora* as recently as February of the present year. Dr. Regel was the recipient of many honours in his adopted country, and he was elected a foreign member of the Linnean Society of London in 1890. This is the second of her few prominent botanists that Russia has lost within a year.

NOTES.

THE annual meeting of the Iron and Steel Institute will be held at the Institution of Civil Engineers, 25 Great George Street, London, on Thursday and Friday, May 26 and 27, commencing each day at 10.30 a.m. Sir Frederick Abel, F.R.S., the President, will deliver an address on Thursday, May 26. The following papers will be read and discussed on the same day, as far as time permits:—(1) On experiments with basic steel, by W. H. White, F.R.S., Director of Naval Construction and Assistant-Controller of the Navy; (2) on the production of pure iron in the basic furnace, by Colonel H. S. Dyer, Elswick Works, Newcastle-on-Tyne; (3) on experiments on the elimination of sulphur from iron, by E. J. Ball, and A. Wingham, London; (4) on platinum pyrometers, by H. L. Callendar, London. On Friday, May 27, the following papers will be read and discussed:—(5) On the manufacture and application of chilled cast iron (Gruson's system), by E. Reimers, Technical Director of the Gruson Works, Madgeburg; (6) on valves for open hearth furnaces, by J. W. Wailes, Calderbank, near Glasgow; (7) on the calorific efficiency of the puddling furnace, by Major Cubillo, Trubia Arsenal, Spain; (8) on a practical slide-rule for use in the calculation of blast furnace charges, by A. Wingham, London; (9) notes on fuel, and its efficiency in metallurgic operations, by B. H. Thwaite, Liverpool.

THE annual meeting of the Society of German Men of Science and Physicians will be held at Nürnberg from September 12 to 18. At the same time and place there will be a meeting of the German Mathematical Association. In connection with these meetings there will be a mathematical exhibition, including models, drawings, apparatus, and instruments used in teaching and in research in pure and applied mathematics. The project has the support of the Bavarian Government, and those who are organizing the exhibition have secured the co-operation of various competent men of science, and of the mathematical departments of some colleges, besides that of prominent publishers and well-known technical institutions. Space will be granted free of charge to exhibitors.

PROF. ELISHA GRAY, Chairman of the Committee on the Electrical Congress to be held in connection with the Chicago Exhibition, is about to visit all the important electrical centres in the Old World. He will attend meetings of the different electrical organizations, and hopes to strengthen the interest of European electricians in the Exhibition.

WE learn from *Science* that Mr. Timothy Hopkins has made provision for the endowment and maintenance of the seaside laboratory at Pacific Grove recently established under the auspices of the Leland Stanford Junior University. The Hopkins Laboratory will be under the general direction of Profs. Gilbert, Jenkins, and Campbell. It will be open during the summer vacation, and its facilities will be at the disposal of persons wishing to carry on original investigations in biology, as well as of students and teachers. Microscopes, microtomes, and other instruments necessary for investigations will be taken from the laboratories of the University.

THE great surgeon Richet has been succeeded in the Paris Academy of Sciences by Dr. Guyon.

THE distinguished mycologist, M. Roumeguère, of Toulouse, died on February 29 at the age of sixty-three. He had been for fourteen years sole editor of the quarterly *Revue Mycologique*, and was the author of a number of mycological works, the best-known being "Cryptogame illustrée, Champignons d'Europe," with 1700 illustrations.

AN interesting course of lectures is being delivered in connection with the Palestine Exploration Fund. They are being given in the lecture-room of the Royal Medical Society. On Tuesday, Canon Tristram lectured on the natural history of Palestine. The following are the remaining lectures of the course:—May 31, twenty-seven years' work, by Mr. Walter Besant; June 7, the Hittites up to date, by Dr. W. Wright; June 21, the story of a "Tell," by Mr. W. M. Flinders Petrie; June 28, the modern traveller in Palestine, by Canon Dalton.

THE members of the Geologists' Association will make an excursion to Down on June 18. The directors will be Mr. W. E. Darwin and Mr. W. Whitaker, F.R.S. Having arrived at Urpington, the party will walk up the valley to Green Street Green, where shells and bones have been found in the gravel that forms the bottom of the dry upper part of the valley of the Cray. The walk will be continued through High Elms Park to Down (3½ miles from the station). From Down a short stroll eastward gives a good view of a fine chalk valley. An opportunity will be taken for examining the clay-with-flints which caps the chalk over the higher grounds. The formation of this clay will be discussed, with a notice of Darwin's remarks thereon, and with reference to other like deposits. The general geology of the district will also be described, and the marked features caused by the clayey covering over the chalk, by the fine escarpment of the lower London Tertiaries, and by the London Clay hills beyond. By permission of Mrs. Darwin, the house and grounds rendered classic as the residence of Charles Darwin (Down House) will be shown to members, and Mr. De B. Crawshay will exhibit specimens of the flint implements that have lately been found over the high grounds of the neighbourhood. Messrs. Allen will exhibit others. The return journey will be made across the Tertiary escarpment at Holwood Park, and then down the dip-slope of the Blackheath Beds, over Hayes Common to Hayes (a walk of four miles).

ON Saturday afternoon, May 28, Prof. H. Marshall Ward will begin at the Royal Institution a course of three lectures on some modern discoveries in agricultural and forest botany.

ORCHID-LOVERS find much to admire in the latest of Mr. William Bull's exhibitions. An enthusiastic writer in the *Times* describes Mr. Bull's orchid-house as "at present a dream of beauty."

EARLY on Tuesday morning some parts of West Cornwall were visited by an earthquake. The *Times* says that in the village of Manaccan, in the Lizard district, the shock was so severe that the villagers almost without exception were awakened from their sleep by the shaking of their beds and the rattling of articles in their rooms. Their houses, too, distinctly shook, and in one case a person who was awakened from his sleep saw the door of his bedroom thrown wide open. At Redruth, some 12 or 15 miles distant, the shock was also felt. At first it was thought there had been an explosion somewhere in the neighbourhood.

DURING the past week a complete change of weather conditions has taken place over the British Isles. The anticyclone which had lain over the country with such persistency for several weeks showed signs of giving way on the 12th, and during the two following days a large but shallow depression spread over the kingdom from west and north-west, while the wind shifted to south-westward with unsettled and showery weather. The temperature, though cooler, was somewhat high for the time of year, the maxima varying from nearly 60° over Scotland to 65° and 70° over England and Ireland. Solar halos were observed on several days, and thunder was reported from the North Foreland on the 13th. Subsequently the westerly winds increased in force, especially in Ireland, and the sea became rough on our exposed western coasts. Some decrease of temperature also occurred, the maximum readings after Sunday only reaching about 60° in a few places. The conditions have been favourable to rain, but the fall has been slight, except in the north and west, and there is still a large deficiency in nearly all parts of the United Kingdom.

The Royal Meteorological Society has published a third edition of "Hints to Meteorological Observers" (42 pages large octavo). It is pointed out in the preface that meteorological observations, to be of scientific value, must be made on a uniform plan, otherwise the results will not be mutually comparable. The directions given are clear and concise, and the various instruments, both desirable or necessary, for a station of the second order, at which observations are taken at least twice daily, are plainly illustrated. The work also comprises several tables which are essential to the proper reduction of the observations recorded. No one can doubt that, notwithstanding the regulations laid down by several Conferences, there is still want of uniformity, not only when comparing observations of one country with another, but even among the observers of our own country. Take, for instance, the observation of rainfall, temperature, sunshine, cloud, and fog. It would be easy to show that the methods employed by various observers differ considerably, especially as to what constitutes a rainy day and how snow is measured, while the estimation of fog is very uncertain. Sunshine values by various kinds of instruments are hardly comparable *inter se*, and the accurate observation of clouds, whether of height, motion, amount, or description, is undoubtedly difficult, and presents a stumbling-block to many observers. Therefore, we cannot but welcome the exertions of the Meteorological Society to obtain uniformity. The work in question will be found very useful for the purpose, and might perhaps be rendered more so, in future, by the addition of the most approved pictures of clouds, and fuller information as to the importance of their careful observation.

The Report of the Department of Marine (Ottawa) for the fiscal year ended June 1891, contains a report upon the Meteorological Service of Canada for the period extending from October 1, 1890, to October 31, 1891. This Service is divided into two branches: (1) the collection and utilization of observations taken simultaneously for the purposes of weather prediction, and (2) the reduction of observations taken by volunteer observers and others for climatological purposes. The publication of the results obtained from the second division has been continued annually, since the establishment of the Service in 1872; but it is now proposed to deal with the accumulated observations, and to publish them in a serviceable and readable form. This will be the first authoritative Government publication on the climate of Canada; and it will be useful for immigration purposes, and for showing the suitability of the climate, in various localities, for raising agricultural crops. It is expected that the work will require three years to complete. Among the stations in connection with the Canadian Service is one at Bermuda, towards the maintenance of which an annual contribution is paid to the Government of that island, and cable messages are received daily in the interests of the shipping on the Atlantic coast. The Cable Company transmit the messages at half the ordinary rates. Many severe storms have occurred in Canada since the last report, and in each instance warnings were issued from Toronto; of these 80·7 per cent. are stated to have been verified. Warnings of approaching snowstorms were also issued to railways, and it is proposed to extend this service to Manitoba, and as far west as Qu'Appelle.

An excellent paper on "The Art of Internal Illumination of Buildings by Electricity," was read by Mr. W. H. Preece, F.R.S., in the rooms of the Royal Institute of British Architects on Monday evening. In the course of his remarks Mr. Preece noted that the electric light was not always absolutely safe. Security was to be obtained only by good design, perfect materials, first-class workmanship, and rigid inspection. Imperfect materials erected by cheap contractors had led to many disasters. On the other hand, it was stated that no fire had occurred in buildings fitted up under the rules and regulations, and inspected by the officers, of the insurance companies in this country. In Mr. Preece's opinion, everything ought as much as possible to be kept in view, and the conductors ought not to be hidden under wainscots or floors or above ceilings. The glow lamp excited by three watts per candle was at present the most perfect source of domestic light, and when the patent expired—in a year or two—would be obtainable at about one-third of the present price.

Mr. W. B. L. Hamilton, writing in the American journal *Electricity* on "Electricity in the United States Navy," says the latest use of the electric motor in taking the place of human energy in the manipulation of the death-dealing Gatling gun has been found to work with great success. The Crocker-Wheeler Motor Company, at the request of the United States Navy Bureau of Ordnance, constructed a special type of motor, which is attached to the breech of the gun. Hitherto the services of two men have been necessary in the working of these guns—the gunner, whose duty is to train the gun and drop the shot, and another man to operate the crank which sets in motion the mechanism which causes the balls to hail down upon the enemy. The adaptation of the Crocker-Wheeler motor not only does away with the services of the latter, but enables the gunner to train and operate the gun at will by touching an electric button. So completely is the Gatling gun under the control of the gunner, that he is enabled to fire either a single shot, or to fire them at the rate of 1200 per minute.

Science of April 29 prints the following account of a fire-ball, by C. C. Bayley:—"A telephone wire was supported on cedar posts 20 feet high and 20 rods apart. During August, 1889, we had a thunderstorm, during which there was a sharp and heavy crash. Several of the poles were found to have been struck, and portions to have been taken out through their entire length. One of these portions, of the size of a medium rail, was thrown into an adjoining field some rods from the pole. Portions from the others were smaller and more or less shattered. Near the southernmost pole struck, a family were in a house with doors and windows open, and a luminous ball seemed to leap from the wire, pass through the open door and a window, and pursue its course some rods through the open space behind the house. A boy in the room grasped his thumb and cried out, 'I'm struck,' and Mr. Hewett felt a sensation of numbness in his left arm for some time. A girl seized her shawl and rushed out of the house to chase the ball. She reported that she pursued it some distance, while it bounded lightly along, until it seemed to be dissipated in the air without an explosion. The size of the ball was about that of the two fists, and its velocity about that of a ball thrown by the hand."

We learn, from a Florentine source (*La Nazione*, May 3), that in the spring of the year 1890, Mrs. Zelia Nuttall, of the Peabody Museum of American Archæology and Ethnology, Cambridge, Mass.—whose interesting memoir on "Ancient Mexican Shields" was recently noticed in these columns—recognized the great importance of an anonymous Spanish-Mexican MS. preserved in the National Central Library of Florence.

This MS. has never been published. It is entitled "Libro de la vida que los Yndios antiguamente hazian, y supersticiones y malos ritos que tenian y guardavan" (*MSS. Magl.*, Class III., Pal. 11, Cod. 3). It treats of the costumes and religious rites of the ancient Aztecs, and is full of coloured designs which Mrs. Nuttall has had reproduced in *fac-simile* by photographic lithography. It is her intention to publish this MS., at her own cost, accompanied by a preface, an English translation of the text, and illustrative notes. It will be dedicated to the approaching Congress of Americanists, which will be held in Spain this autumn to celebrate the fourth centenary of the discovery of America. An edition of 200 copies will be issued, and held on sale at the Peabody Museum of American Archæology.

An interesting paper on the uses and applications of aluminium was read by Mr. G. L. Addenbrooke before the Society of Arts on May 11, and is printed in the current number of the Society's Journal. Referring to the applicability of aluminium to opera and field glasses, he said there was an example on the table of a glass made in 1864, which had ever since been in constant use. In 1870 the wheel of a carriage passed over it, but it was afterwards straightened out and made usable. It has made two voyages across the Atlantic, two across the Pacific, and has had other shorter experiences of the sea air, besides lying on one occasion for some time in salt water. Mr. Addenbrooke has kept strips of aluminium for two or three weeks in salt water, and has noted very little effect.

Towards the end of last year—from November 21 to December 5—the members of the Victoria Field Naturalists' Club made an excursion to the Australian chains of hills called the Grampians. The excursion seems to have been remarkably pleasant, but the scientific results did not quite come up to the expectation. According to an account given in the Club's Journal, the botanists were far and away the most successful. A really good collection of plants of the district was obtained. In bird life there was little observable that is not so elsewhere nearer Melbourne; neither was there any great variety of snakes or lizards, and to the collectors of these, as also to the entomologist, the excursion was especially disappointing. From the well-known extensive variety of flowering shrubs in the Grampians, coupled with the fact that several are peculiar to the district, it was fully expected that at least a few clearly representative Lepidoptera or Coleoptera would be secured, but not a specimen of either family was seen that is not common in and around Melbourne.

Mr. E. H. Parker, the British Consul at Kiungchow, in Hainan, a large island off the southern coast of China, mentions a curious phenomenon in connection with the tides of that port. The tides inside the inner harbour, he says, require several years of careful observation before they can be tabulated. It appears certain, however, that there are always two tidal waves a day, though one is so much more considerable than the other that the effect is often practically that of one single tide in the twenty-four hours. The easterly and westerly currents through the straits are not necessarily connected with the rise and fall of the water, either there or in port. The phenomenon of "slack water" (*morte eau*) is also observable every ten days or so at Haiphong, and is probably owing to much the same causes as at Hoihow. At Tourane in Tonquin, too, it is popularly thought that there is usually but one tide within the twenty-four hours. This tide is felt away up to the citadel of Quangnam. In the Gulf of Tonquin the incoming tidal wave flows from the south, a fact which perhaps accounts for the singular circumstance that the westerly current in the Hainan Straits always sets for sixteen hours. One at least of the tidal waves from the east which pass Hoihow cannot get through the straits to Tonquin so soon as that portion of the same wave which takes a circuitous course by way of Annam.

The Pacific Coast Fisheries of the United States appear to be in a most flourishing condition. According to a recent census bulletin, they employed 13,850 persons in various capacities in the last federal census year; 6,498,239 dollars were invested in them, and the products were valued at 6,387,803 dollars. The canning of salmon is the most important fishery industry in the Pacific States.

Sisal grass, according to a Mexican authority quoted in the new number of the *Board of Trade Journal*, is likely to prove a very important source of wealth for Mexico. It grows in long, narrow blades, often to the length of four or five feet, and these, when dry, curl up from side to side, forming a flexible string, stronger than any cotton cord of the same size ever manufactured. It is in great demand among florists and among manufacturers of various kinds of grass goods; and it is said to be capable of being applied to many new uses. Ropes, cords, lines of any description and any size may be manufactured of it, and a ship's cable of sisal grass is one of the possibilities of the future. It is almost impervious to the action of salt water, and is not readily decayed or disintegrated by moisture and heat. It takes its name from the port of Sisal, in Yucatan, through which it was formerly exported.

A paper on modern aërial navigation was read by Captain J. D. Fullerton, R.E., before the Royal United Service Institution on Friday last. His object was to show that the science of aëronautics was based upon simple rules and common sense, and not upon wild and vague theories opposed to all principles of nature. He divided aërial navigation into two distinct branches: (1) ballooning, or navigation by means of machines lighter than air; and (2) aëration, or navigation by means of machines heavier than the air. Proceeding to discuss the first branch, the lecturer sketched the history of attempts at propelling balloons. Describing the requirements of a proposed war balloon, he said these were: (1) that it should be able to carry three or four passengers, a supply of explosive shells, and a machine gun or two; (2) that it should be able to travel at the rate of about 30 miles an hour on a still day, which would enable it to keep up with almost any warship afloat. In regard to aëration, Captain Fullerton said the chief characteristics of this system were that a large supporting surface, either in the form of wings or in that of an aëroplane, was used to carry the weight; that the lifting or supporting power of this surface was dependent upon its velocity and the angle of inclination which it made with the horizon; and that the horizontal resistance to motion depended upon the velocity and angle of inclination in the same manner. The great difficulty both in ballooning and aëration was to get a sufficiently light motor.

The first number of a new journal, called the *Canal Journal*, has been issued. Its aim will be "to assist the cause of canals and inland navigation generally." It promises to be of considerable value and interest to the class of readers for whom it is especially intended.

The German publisher, Friedrich Brandstetter, announces that he will issue in the course of the present year a second and improved edition of Dr. J. J. Egli's "Nomina Geographica." The number of explained names has been much more than doubled.

Further details concerning the nature and chemical behaviour of acetyl fluoride, CH_3COF, the new substance whose preparation and physical properties were described in our note of last week (p. 40), are contributed by M. Meslans to the current number of the *Comptes rendus*. It may be remembered that this interesting substance was shown to be liquid at temperatures below 19°·5, and gaseous at temperatures superior to this, its temperature of ebullition, both the liquid and the gas being colourless, and endowed with an odour somewhat reminding one of that of carbonyl chloride. In contact with water, acetyl fluoride is found to react eventually in a manner similar to its well-known analogue, acetyl chloride, forming hydrofluoric and acetic acids.

$$CH_3.COF + H_2O = CH_3.COOH + HF.$$

But there is a considerable difference in the degree of energy with which the decomposition occurs, for while the behaviour of acetyl chloride is almost violent, acetyl fluoride only reacts with great slowness. When a small quantity of the fluoride if dropped into water the two liquids do not mix, and the globule of fluoride only disappears after long standing. Strong solutions of potash or soda, however, decompose it rapidly, with formation of fluoride and acetate of the alkali. The action of caustic lime upon acetyl fluoride is interesting; the gas is rapidly absorbed by it, and calcium fluoride and acetic anhydride formed.

$$2CH_3.COF + CaO = CaF_2 + (CH_3.CO)_2O.$$

Ammonia gas reacts with considerable energy with the liquid, producing a white crystalline mass, consisting of ammonium fluoride and acetamide, $CH_3.CONH_2$. The latter may readily be isolated in good crystals by extraction with ether and subsequent evaporation. The gaseous fluoride reacts with ammonia in the proportion indicated by equation—

$$CH_3.COF + 2NH_2 = CH_3.CONH_2 + NH_4F\ ;$$

that is, two volumes of ammonia react with one volume of acetyl fluoride gas. Aniline likewise acts with energy upon the liquid, forming hydrofluoric acid and acetanilide, $C_6H_5.NH.CH_3.CO$. The action of absolute alcohol is peculiar; it dissolves the liquid fluoride in all proportions, but after an interval of a few hours, interaction occurs with production of hydrofluoric acid and acetic ether. The latter may readily be separated by the addition of water.

$$CH_3.COF + C_2H_5OH = CH_3.COOC_2H_5 + HF.$$

Acetyl fluoride is much more stable in presence of alkaline acetates than its chlorine analogue. Even after four hours' heating in a sealed tube to 100° with sodium acetate, only a small proportion of sodium fluoride and acetic anhydride were formed. Still more stable is acetyl fluoride towards sodium amalgam, there being no appreciable reduction to aldehyde or alcohol. Metallic sodium is likewise without action upon liquid acetyl fluoride, but when heated to redness in the gaseous fluoride, the metal decomposes it with incandescence, sodium fluoride being formed and carbon deposited, together with a few drops of a liquid whose characters have not yet been ascertained. From these reactions it is evident that acetyl fluoride is a substance of a much more stable character than its analogue, acetyl chloride.

THE additions to the Zoological Society's Gardens during the past week include an Egyptian Ichneumon (*Herpestes ichneumon*) from North Africa, presented by Dr. J. Anderson; a Ring-tailed Coati (*Nasua rufa*), a Kinkajou (*Cercoleptes caudivolvulus*), a Blue-bearded Jay (*Cyanocorax cyanopogon*) from Brazil, presented by Mr. J. E. Wolfe, C.M.Z.S.; two Laughing Kingfishers (*Dacelo gigantea*), from Australia, presented by Mrs. H. M. Stanley; two Grey Hypocoliuses (*Hypocolius ampelinus* ♂ ♀) from Scinde, presented by Mr. W. D. Cumming; two Ravens (*Corvus corax*), British, presented by Mr. Gregory Haines; a Crowned Horned Lizard (*Phrynosoma coronatum*) from California, presented by Mr. R. Thorn Annan; a Common Fox (*Canis vulpes*), British, three Palm Squirrels (*Sciurus palmarum*) from India, a Brown-throated Conure (*Conurus æruginosus*) from South America, deposited; a Grey-headed Porphyrio (*Porphyrio poliocephalus*) from Persia, purchased; a Persian Gazelle (*Gazella subgutterosa* ♂), a Vulpine Phalanger (*Phalangista vulpina* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

LATITUDE OBSERVATIONS AT WAIKIKI.—The *Hawaiian Gazette* for March 8 contains an account by Mr. Preston, of the U.S. Coast Survey, of the latitude observations which are being made at Waikiki on the island of Oahu, Hawaii. In it we read:—"The motion of the pole is, of course, extremely small, and the effect is that here in Honolulu we are about 50 feet nearer the equator now than we were some months ago. This change does not, however, go on indefinitely, but the motion is such that the pole returns at the end of a year to nearly its original position. Besides this annual movement, there seems to be reason to believe that there is a secular change extending over a period of at least sixty years." But no definite conclusions can be arrived at until the observations made at Honolulu are discussed in connection with those made on this side of the earth. In order to test the theory that changes of latitude are produced by the movements of large masses of molten matter in the interior of the earth, the force of gravity is measured on every night that latitude observations are made. As this is done with the idea of detecting variations, the relative and not absolute intensity is all that is required. The arrangement employed is such that if from any cause the acceleration due to gravity should be increased by only one five-hundredth of an inch, it could be easily measured. The observations will be completed in the fall of the year, but the final results cannot be known before the latter part of 1893.

MOTION IN THE LINE OF SIGHT.—*Astronomy and Astro-Physics*, No. 104, contains a very important contribution by Mr. W. W. Campbell, on the reduction of spectroscopic observations in the line of sight. The paper contains an explanation of the construction and use of the tables, the limit of precision adopted being one-hundredth of a mile per second. The first table gives the velocities of the star corresponding to a known displacement of one tenth-metre in the various parts of the spectrum, from which the velocity corresponding to any observed displacement can be directly obtained. The formula

$$v_s = V_s \Delta\lambda$$

gives this velocity corresponding to any measured $\Delta\lambda$, V_s being taken directly from the tables.

Table II. gives the earth's orbital velocity, V_a, and the deviation, i, when the sun's longitude is $\odot$. These values are obtained from the formulæ—

$$\tan i = \frac{e \sin(\odot - \Pi)}{1 + e \cos(\odot - \Pi)}$$

and $$V_a = \frac{a}{\sqrt{1 - e^2}} \cdot \frac{2\Pi}{T}[1 + e \cos(\odot - \pi)] \sec i,$$

and when found are substituted in the equation—

$$v_a = - V_a \sin(\lambda - \odot + i) \cos \beta.$$

By tabulating V_a and i as functions of $\odot$, their values can be very easily found, and v_a consequently reduced from the last-mentioned equation.

The value of the lunar correction has been taken into account here, omitting any errors due to ellipticity of the orbit and its inclination to the ecliptic. Its value is obtained from the formula—

$$v_d = - 0{\cdot}29 \sin t \cos \delta \cos \phi,$$

the latitude used being that of Mount Hamilton, but corresponding corrections for any other latitudes can be found from these by multiplying them by $\frac{\cos \phi'}{\cos \phi}$, where ϕ' is the new latitude required.

THE LATE PARTIAL ECLIPSE OF THE MOON.—Fine weather was generally prevalent during the partial eclipse of the moon on May 11, affording many observers a good opportunity for noting any new features connected with such an occurrence. Considering that the eclipse was only a partial one, it may be rather difficult to decide whether it should be classed in the category of "bright" or "dark" eclipses. Undoubtedly it was not a very dark one, for during the greatest immersion the whole surface of the moon could be distinctly seen, especially with the help of a telescope, with which craters could be picked out. On the hypothesis that "dark" and "bright" eclipses are brought about owing to the different states of the solar atmosphere, the present one should have been at any rate more inclined to be "bright" than "dark," for as we are approaching a spot maximum the sun's atmosphere is becoming more and more disturbed. At the time of greatest obscuration the blood-red tinge, caused by the absorption of our atmosphere, became very apparent, but this gradually wore off as the brighter part of the moon made its appearance.

From a series of photographs of the eclipsed moon taken at intervals of about a quarter of an hour, the penumbra in some of them was very distinct, especially in those taken near the time of greatest obscuration, the exposures then being comparatively long. At mid eclipse an attempt was made to obtain a photograph of the whole disk of the moon, as it appeared so distinct and clear on the ground glass, but even an exposure of 12s., using extra rapid dry plates and a 30-inch reflector, was not sufficient to bring it out, although the extent of the bright crescent and penumbra was very much increased.

DECLINATIONS OF STARS FOR REDUCTION OF VARIATIONS IN LATITUDE.—No. 263 of the *Astronomical Journal* contains the declinations of thirty-six stars, which have been obtained with the prime-vertical transit of the United States Naval Observatory. The observations were made for the determination of the constant of aberration, and consequently at the periods of maxima aberration effects, but their present publication, as Prof. S. J. Brown states, is owing to the "many requests for the observed declinations of these stars for use in discussing probable secular and periodical changes in latitude." The stars in this list are comprised in the zone 36° 37′—38° 40′. The communication contains a brief account of the methods of reduction employed, together with a reference to the instrumental adjustments.

The same number of the *Journal* contains also some results of the observations of α Lyræ, made during the years 1862–67 with the same instrument as mentioned above. The discussion of these observations was first made when Euler's value of 306 days for the periodical variation of the latitude was in vogue, but Prof. S. Newcomb, in the present case, has taken Mr. Chandler's new value, and gives, briefly, the following results :—

Mean declination of α Lyræ for 1865·0, assuming the latitude of the centre of the Observatory to be 38° 53′ 39″·25	38° 39′ 35″·56
Correction to Struve's constant of aberration...	+ 0″·006
Hence, constant of aberration	20″·451
Parallax of α Lyræ	+ 0″·24
Coefficient of sun's azimuth in declination ...	+ 0″·507
Coefficient of sin N	$s = + 0''\cdot086$
Coefficient of cosine N	$c = - 0''\cdot087$

the value of N being assumed zero at 1864·50, increasing 308° annually.

The expression which he gives for the variation of the latitude of Washington is

$$\delta\phi = 0''\cdot122 \cos 308^\circ (t - 1864\cdot94),$$

the distance between the poles, or the semi-amplitude of the variation of the latitude, being 0″·122.

COMET 1892 DENNING (MARCH 18).—The following elements and ephemeris are given for this comet in the *Astronomische Nachrichten*, No. 3089, computed from three observations made at the Hamburg Observatory :—

$$T = 1892 \text{ May } 11\cdot22042 \text{ Berlin M.T.}$$

$$\left.\begin{aligned} \omega &= 129^\circ\ 18'\ 34''\cdot4 \\ \text{☊} &= 253\ \ 25\ \ 41\cdot6 \\ i &= \ \ 89\ \ 42\ \ \ \ 4\cdot3 \end{aligned}\right\}\text{ M. Equator } 1892\cdot0.$$

$$\log q = 0\cdot294619;$$

Ephemeris for 12h. Berlin M.T.

COMET 1892 SWIFT (MARCH 6).—The elements and ephemeris of this comet are given in the *Edinburgh Circular* (No. 26), from which we make the following extract :—

1892.	R.A. h.	m.	s.	Decl. °	′	log Δ.	log r.	Br.
May 19	23	23	44	+31	52·2			
20		26	16	32	22·2			
21		28	47	32	51·6	0·1522	0·1035	0·53
22		31	16	33	20·4			
23		33	44	33	48·7			
24		36	10	34	16·5			
25		38	34	34	43·7	0·1628	0·1166	0·47
26		40	56	35	10·4			

The brightness at the time of discovery is taken as unity.

The comet is situated in the constellation of Pegasus, and on the 22nd will form very nearly an isosceles triangle with β Pegasi and α Andromedæ, the comet then lying nearly midway between η Pegasi and σ Andromedæ.

GEOGRAPHICAL NOTES.

M. LOUIS LÓCZY, in his annual address to the Hungarian Geographical Society at the commencement of the current session, expressed surprise that scientific geography was so little appreciated in England. "It is sad to see," he said, "that, despite the efforts of the oldest of Geographical Societies, the great Universities of Oxford and Cambridge have not yet established chairs of geography, and that lectureships even have only been established with difficulty."

IN the Report of the Mississippi River Commission, the extent of the levees confining the river below Cape Girardeau (Missouri) is given as 1300 miles. During the high water of 1891, the levees gave way in five places, and the total length of the breaches made in the embankment was about one mile. By far the most serious gap was that at Ames Plantation, opposite New Orleans, which attained a width of 1665 feet, and a maximum discharge of about 91,000 cubic feet per second. It overflowed 2000 square miles, one-tenth being cultivated land. The cause of this crevasse was a badly constructed rice-flume, and as the great Nita crevasse of 1890 had a similar origin, the Commission has resolved to discountenance the use of such flood-gates in future. All of the crevasses of 1891 put together discharged less water than the Nita crevasse alone in the previous year, and it was only one out of about fifty breaks which occurred during the great floods.

A NEW map of Dahomey, on the scale of 1 : 500,000, has been prepared by M. A. L. d'Albeca, and published as a supplement to the new journal, *La Politique Coloniale.* All available data have been employed in its preparation, much being of course derived from itineraries unchecked by observation.

CAPTAIN GALLWEY, Vice-Consul for the Oil Rivers Protectorate, has succeeded in tracing a channel navigable for canoes through the deltaic swamps between Benin and Lagos, a distance of 160 miles.

THE *Proceedings* of the Royal Geographical Society for May contains a letter from Mr. Gilbert T. Carter, Governor of Lagos, describing a recent journey into the interior. From the summit of a hill near Ode Ondo he obtained a magnificent view to the south-east over a foreground of rocky forest-clad hills, backed by a fine range of mountains about twenty miles away, which have not previously been reported. The height of the most conspicuous summits is estimated to be from 5000 to 8000 feet above sea-level.

THE VARIATION OF TERRESTRIAL LATITUDES.

IN a letter addressed to M. R. Radau by M. Antoine d'Abbadie, which appears in the March number of the *Bulletin Astronomique*, the writer gives an interesting historical account of the work that has been done with regard to this question. As it contains also some suggestions for future work, the following *résumé* may be of service.

The author states that M. Fergola, the astronomer at Naples, may be looked upon as the one who first drew attention to this question. Of the earlier astronomers, Sir George Airy was led to the conclusion that the latitude was subject to a slight variation, and he published in 1854 and 1875 the greatest and least values for the co-latitude 38° 31′ 22″·16, and 38° 31′ 21″·35 respectively, obtained from observations of the pole. Many other results were obtained by him, which caused him to assign reasons for the fluctuations, but he deemed it wiser to publish the results at a time when the measurement by graduated circles was considered more concise.

One of the first causes to which these variations were attributed was refraction, and it was with the intention of settling this point that Airy undertook with his zenith telescope the measurements of the zenith distance of γ Draconis, as this star culminated near the zenith at Greenwich. M. Faye, towards the year 1846, found out the advantages of such an instrument as that used by Airy, and his installation was composed of three instruments, a zenith telescope, a mercury trough, and a nadir telescope, the last two of which provided a means of obtaining the true nadir point.

Porro, an Italian officer, adopted several of these improvements in his instrument: he added to his telescope a trough with a glass bottom, the plane surface of which was placed in a horizontal position, and reflected feebly the image of the central thread of the zenith telescope. By filling the trough with water, another image of the same wire was obtained, which remained visible during the transit of the star, and it was possible to take several measures of the distance between the star and image.

The next observer we find occupied in this research was Respighi, who, in the year 1872, published the nadir distances of several stars measured at Rome. The stars he observed were those which culminated so near the zenith that they could be seen in the telescope after reflection from mercury. From a series of seventy-seven observations, taken during five months of the year 1869, he observed the transits of two stars reflected at his nadir. During this interval he found a difference of 2″·07 between the greatest and least of his results.

In the method of Horrebow, the divided arc on his instrument gave a rough reading of the inclination of his telescope, while for greater precision he used the readings taken from a level fitted to the telescope.

M. d'Abbadie here condemns the use of levels altogether for really accurate work, and backs his opinion with facts which he has obtained from personal experience. He mentions that, as far back as 1837, he made a study of their accuracy, but the levels he used were not good ones. Later, after having purchased some from the best-known makers in Paris, Munich, London, and Hamburg, he repeated his experiments in a cellar in an old *château*, and he found that the results given were of a most unsatisfactory kind.

Admitting, then, that there was a variation in the latitude, it was not long before periods were established. Peters, in the year 1845, from observations at Pulkova, derived one of 303·9 days with a maximum on November 16, 1842. Mr. Nyrèn extended this to 305·6 days, with a maximum on December 13, 1867, while Mr. Downing, from ten years of observations made at Greenwich, deduced a period of 306·0 days, with a maximum on October 12, 1872. Leverrier, and Hough at Albany, also found variations that were confirmed at Abbadia.

M. d'Abbadie then refers to the variation of the true azimuth, which, as he says, did not escape the notice of Airy. In the year 1848 he estimated it as 4″ or 5″, while fifteen years later he extended it to 6″ or 7″. Of course, if the pole suffers any displacement, such as an increase in elevation, at its two elongations it will be displaced by the same amount, and the azimuths in these cases would be increased. The greatest displacement we have mentioned is 2″·07, but M. d'Abbadie says "that if, by hypothesis, the north pole of the earth be elevated by 7″ by approaching the actual zenith, the true azimuth will be diminished by those 7″ in a place situated at 6h. om. of west longitude, and increased by the same quantity at 6h. om. of east longitude." He then states how, if the pole was considered movable for places situated at opposite ends of a diameter of the earth, the values for the variation should be the same, but of opposite signs. To establish coincidences of this kind, it is suggested that observers in Asia and America should take their nadir readings at the same time as they are taken at Abbadia —that is, in the morning and evening at 6h. Paris mean time. The results Chandler obtained from his latitude observations indicated a minimum on September 1, 1884, and a maximum on May 1, 1885, with a difference of about 0″·7. By taking the 6 o'clock p.m. P.M.T. observations made at Abbadia, it was found that a maximum value was obtained on September 1, 1884, and a minimum on May 1, 1885, with a difference of 0″·74. Contemporary observations made at Berlin and Honolulu tended also to the same conclusion; but in spite of them M. d'Abbadie does not think it prudent to suppose a fluctuation of the earth's axis.

After referring to some sudden changes that this variation has undergone, he goes on to mention Darwin's, Wolf's, and Paschwitz's instruments that were constructed for the measurement of very small displacements. The last-named modified to a large extent Zöllner's horizontal balance, and added to it a mirror, obtaining in this way, by the employment of photography, a continuous series of curves.

Mr. Nobile, in his memoir of 1883, related that, in 1820, Brioschi believed in the small changes in the terrestrial latitudes, and admitted two possible variations, one secular and another periodic. He states, also, that Fergola, in 1871, supported this idea of Brioschi; and Peters, as well as Nyrèn and Gylden, confirmed this opinion. Euler and Legendre are also said to have concluded from theory such a variation, giving it a period of ten months.

Another memoir by M. Nobile, contains a discussion on the observations that were made with the object of determining the latitude of the Observatory at Capo di Monte, near Naples, and from these, together with some others, he deduced a tendency in the latitude to increase in the summer and decrease in the winter months.

It will be seen from the preceding summary that very little is definitely known as to the causes of this variation. From the observations just referred to, it seems that refraction would be the cause of such a variation, but as this is not borne out in other observations, new theories must be advanced. M. d'Abbadie, knowing the importance that is attached to the inquiries into the causes of these variations, before concluding his letter adds a few suggestions relative to a means of settling some of these points, and the following is the plan which he proposes should be adopted.

Three observers, A, B, and C, should be provided each with a good zenith telescope; and the same two stars, which it is proposed to use, should be observed by them. B and C should be as near as possible on the same parallel of latitude, so as to have identical refractions when measuring the declination on the meridian of the chosen stars. To insure greater accuracy in these declinations, he suggests that these stars should be observed at their elongations with a geodetical circle, the refraction in azimuth being zero, save in a few rare cases of lateral refraction. The three observers should "notify at once, in a continuous way, if possible, the varying movements of the nadir, and, in every case, these variations at the precise moment where A would observe on the meridian."

To further complete this plan, two other observers, at D and and E, might be added, the former situated at 6h. east, and the latter at 6h. west longitude, in the same relative positions as Paris is to Calcutta and Chicago. The position of E or D could be chosen in the austral hemisphere, in order to determine whether the variation of the nadir agrees with that which should be observed simultaneously in the opposite hemisphere. Still greater advantage would be gained if two other observers, situated at opposite points of the earth, were chosen to observe these phenomena at the same instant. By adopting this plan, a definite control would be had over the hypothesis that the fluctuation was due to the movement of the terrestrial axis, and if only this point could be settled, we should have advanced a considerable step in its solution.

We may mention here that quite recently Chandler has made the remarkable discovery that the earth's axis of rotation revolves round that of her maximum moment of inertia in a period of 427 days. This, as Prof. Newcomb says, seems at first to be quite contrary to the principles of dynamics, but, after having investigated the theory, he finds that it is in perfect harmony with the amount that the latitude varies, taking into account the elasticity of the earth itself and the mobility of the ocean. Radau's investigations were based on a 306-day period, but he showed that the observed discordances would have to be multiplied three times before they agreed with those obtained by theory.

W. J. L.

MAGNETIC VARIATIONS.[1]

IN this paper the author refers to the ordinary variations of the magnetic elements as observed at Greenwich; the annual progressive change; the diurnal variation—large in summer, small in winter, and also larger when sun-spots are numerous and smaller when sun-spots are few; the irregular magnetic disturbances and magnetic storms, and the accompanying earth currents; phenomena which are generally similar at other places.

He then invites attention more particularly to magnetic disturbances. Those at Greenwich may, after a calm period, arise gradually or commence with great suddenness. When sudden, the movement is simultaneous in all elements. The first indication may be a sharp, premonitory, simultaneous movement, followed after a time by general disturbance, or the movement may at once usher in the disturbance. These initial movements are not always great in magnitude, sometimes, indeed, small, but they have a very definite character, and frequently occur nearly instantaneously, as is shown in the character of the photographic traces.

It has been long known that magnetic disturbances occur at the same time over wide areas of the earth's surface, but the accidental comparison in past years of the times of commencement of one or two disturbances at Greenwich with the times at other places has led the author to suppose that the coincidence in time is much closer than had been before supposed, and the definite, and on occasions isolated, character of the initial movement induced him to undertake the collection and comparison of the times of such movements for a number of days at observatories geographically widely separated.

The times of such movements cannot be caught by eye observation without continuous watching of the magnets, so that the photographic registers have to be relied upon, which is better, excepting that the scale of time is necessarily contracted; but, though in individual measures there might be variations, it was conceived that (supposing no systematic error to exist) the mean of a number of comparisons should give a good result. Seventeen days, occurring in the years 1882 to 1889, were selected for comparison, the observatories being those of Toronto, Greenwich, Pawlowsk, Mauritius, Bombay, Batavia, Zi-ka-wei, and Melbourne, and, for a less number of days, Cape Horn (as obtained from the Mission Scientifique du Cap Horn, 1882–83). It was desired to have times for Pola, but it was found that photographic registers during great part of the period did not exist. The variation in time at each place from the mean of times for all places is given for each day. The mean deviation at the different places varies from + 2·4 minutes to − 2·9 minutes, the agreement between four of the places—Greenwich, Pawlowsk, Mauritius, and Bombay—being very much closer, the mean values of deviation for Greenwich, Pawlowsk, and Bombay differing, indeed, by only 0·1 minute, equivalent to 6 seconds.

The question arises, Are the differences real, or due (considering the contracted time scale) to accidental error? If the magnetic impulse is really simultaneous over the whole earth, it is a striking physical fact, and if not entirely so, the circumstance is no less interesting; but greater attention to accuracy of time scale, or a more extended scale, may be necessary before the point in question can be definitely settled.

A table is added, showing the character of the magnetic movement at the several observatories, from which it appears that at any one place the movements on different days were in most cases similar, though different at different places, indicating on these occasions the occurrence usually of one general type of disturbance.

Reference is made to the question of earth currents. A comparison for thirty-one days, between 1880 and 1891, of cases of sudden magnetic movement and earth current at Greenwich, shows the earth current to precede the magnetic movement by 0·14 minute, equivalent to 8 seconds. The question of the relation between magnetic movements and earth currents is discussed.

The desirability of being able temporarily to obtain, when occasion requires, a more extended time scale for all magnetical and meteorological phenomena is pointed out.

The general result is that in the definite magnetic movements preceding disturbance the magnets at any one place are simultaneously affected; also that in places widely different in geographical position the times are simultaneous, or nearly so, a small constant difference existing at some places which may be real or may be accidental, but the character of which it seems desirable to determine. It is shown also that at Greenwich definite magnetic movements are accompanied by earth current movements which are simultaneous, but that neither magnetic irregularities nor ordinary magnetic variations seem to admit of explanation on the supposition of being produced by the direct action of earth currents.

---

[1] Abstract of paper "On the Simultaneity of Magnetic Variations at different places on occasions of Magnetic Disturbance, and on the relation between Magnetic and Earth Current Phenomena," by William Ellis, F.R.A.S., Superintendent of the Magnetical and Meteorological Department, Royal Observatory, Greenwich. Communicated to the Royal Society, on May 5, 1892, by W. H. M. Christie, F.R.S., Astronomer-Royal.

SCIENTIFIC SERIALS.

American Journal of Science, May.—Radiation of atmospheric air, by C. C. Hutchins. A stream of hot air was arranged so that it could be made to pass in front of one of the faces of a thermopile at a distance of 3 cm., and cause a deflection of a galvanometer needle, or the air could be discharged high above the thermopile, leaving it unaffected except by radiation from a large Leslie cube containing water at the temperature of the laboratory. There was no sort of agreement between measures made on eight different days to determine the absolute radiating power of a column of air 1 centimetre thick at a temperature near 100° C.; but in an ordinary room and under average conditions the value came out = 0·000001133 + 0·0000000711 $(t - t')$, where $t - t'$ is the difference in temperature between the air and the cube. Tyndall's result, that the radiation increases with the amount of moisture in the air, was confirmed, but no exact law of connection between the two was found. This is probably due to the presence of accidental impurities in the air employed. The increase of radiation proves to be proportional to the increase of temperature. There was a small increase of radiating power when sheets of air more than 1 centimetre thick were used; with sheets less than this thickness, no difference of radiation could be detected.—Atmospheric radiation of heat and its importance in meteorology, by Cleveland Abbe. In this interesting and exhaustive paper Prof. Abbe brings together practically all the conclusions that have been arrived at on atmospheric movements and their relation to radiation from the air. In his words, "A comprehensive study of fluid motions shows that air and water alike may be forced to ascend without being warmer and lighter, or to descend without being colder and denser, than the surrounding fluid. The currents and whirls behind any obstacle in streams of air or water are almost wholly independent of differences of density, and are caused by differences of pressure as modified by simple kinetic laws." These motions, which the air is forced to take for purely kinetic reasons, are specially discussed in detail, but it is impossible to enumerate, in an abstract, the many cases considered.—Experiments upon the constitution of certain micas and chlorites, by F. W. Clarke and E. A. Schneider. The minerals analyzed are waluewite, v. of xanthophyllite, clinochlore, leuchtenbergite, diallage, serpentine, and mica from Miask, Ural.—On the qualitative separation and detection of strontium and calcium by the action of amyl alcohol on the nitrates, by P. E. Browning.—The age and origin of the Lafayette formation, by Eugene W. Hilgard.—On the influence of swamp waters in the formation of the phosphate nodules of South Carolina, by Dr. Charles L. Reese. From the experiments it appears probable that both carbonic acid and the humus substances in fresh-water swamps play an important part both in the accumulation and the concentration of calcium phosphate, and thus in the formation of phosphate nodules, these being considered to be phosphatised marls.—Plattnerite, and its occurrence near Mullars, Idaho, by William S. Yeates; with crystallographic notes by Edward F. Ayres.—On the occurrence of Upper Silurian strata near Penobscot Bay, Maine, by William W. Dodge and Charles E. Beecher.—Zinc-bearing spring waters from Missouri, by W. F. Hillerbrand. The chief constituent salt in the spring in question is zinc sulphate. It forms about 56 per cent. of the total dissolved solids.—A meteorite from Central Pennsylvania, by Prof. W. G. Owens. A chemical analysis of the meteorite gave Fe 91·36, Ni 7·56, Co 0·70, P 0·09, S 0·06, Si trace = 99·77.—On two meteoric irons, by G. F. Kunz and E. Weinschenk. One of the masses examined came from Indian Valley Township, Floyd County, Virginia; the other from Sierra de la Ternera, Province of Atacama, Chili.—The molecular masses of dextrine and gum arabic as determined by their osmotic pressures, by C. E. Linebarger. The molecular mass of gum arabic is found to be about 2500, of dextrine 1134, and of colloid tungstic acid 1750. In each of these three cases the colloid molecule is seven times the simple molecule.

American Journal of Mathematics, vol. xiv., No. 2. (Baltimore, Johns Hopkins Press, April 1892.)—The number before us opens with a paper entitled "Some Theorems relating to Groups of Circles and Spheres," by Prof. W. Woolsey Johnson (pp. 97–114). The title at once calls to mind Mr. Lachlan's memoir "On Systems of Circles and Spheres" (Phil. Trans., vol. 177). The author thus puts the connection between the papers: "(1) If there be 5 circles or 6 spheres in each group, the product or determinant of powers is equal to zero; and (2) if there be 4 circles or spheres in each group, the power determinant is the product of two determinants each of which depends upon one of the groups." Mr. Lachlan's results are derived principally from the first of the above theorems, whereas it is Prof. Johnson's object "to point out some other results derivable from the second theorem, and particularly to evaluate the power determinants for groups of smaller numbers of circles and spheres." The two memoirs are an interesting application of a "Theorem in the Geometry of Position" (the multiplication of two determinants) due to Cayley (*Camb. Math. Journ.*, vol. ii., 1841).—The next paper, by C. H. Chapman, is an "Application of Quaternions to Projective Geometry" (pp. 115–40).—Then follows an adaptation of G. W. Hill's method (*American Journal of Mathematics*, vol. i.) "so as to include that class of inequalities which depends also on the ratio of the solar and lunar distances, and, in particular, the principal part of the parallactic inequality," by E. W. Brown. The title of the paper is "On the part of the Parallactic Inequalities in the Moon's Motion, which is a Function of the Mean Motions of the Sun and Moon" (pp. 141–60).—The two remaining papers were read before the New York Mathematical Society, viz. "On the Curves which are self-reciprocal in a Linear Nulsystem, and their Configurations in Space," by C. P. Steinmetz (pp. 161–86); and "A Classification of Logarithmic Systems," by Irving Stringham (pp. 187–94).—This last is an attempt to use the logarithmic spiral, defined as a geometrical locus, as the means for defining the logarithm and demonstrating its properties.

Bulletin of the New York Mathematical Society, vol. i. Nos. 6, 7 (New York: March, April, 1892).—The first of these numbers opens with a discussion of the mechanical axioms, or laws of motion, as presented by Newton. The author, Prof. W. Woolsey Johnson, examines at some length (pp. 129–39) the views put forward in Thomson and Tait, "Natural Philosophy"; Tait, "Mechanics" ("Encyc. Brit."); and Williamson and Tarleton, "Dynamics." The article is a careful piece of reasoning, founded upon the principle that "it is desirable to include among the axioms of mechanics the smallest basis of postulated principles upon which it is possible to construct the science by rigid mathematical reasoning." Then follow short notices of an 8-figure logarithm table, published "par ordre du Ministre de la Guerre, Paris, 1891," and of "An Introduction to Spherical and Practical Astronomy, by Dascom Greene (Boston, 1891)." The usual "Notes" and list of new publications close this number and also No. 7. This last-named number opens with a review of "The Laws of Motion, an Elementary Treatise on Dynamics, by W. H. Laverty." The writer's object in this, and similar articles that are to follow, is "by reviewing somewhat at length a few of the better recent works on elementary mechanics to 'fix the ideas' and arrive at some conclusions, at least, as to what is the best modern usage in treating the subject" (pp. 145–50). The next contribution, by Dr. C. H. Chapman, entitled "Weierstrass and Dedekind on General Complex Numbers" (pp. 150–56), is one of those that makes this *Bulletin* so interesting and valuable to the student. The last article is a translation (pp. 156–68) by Prof. Ziwet of an *éloge* by M. Duhem on "Emile Mathieu: His Life and Works."

Memoirs of the St. Petersburg Society of Naturalists, vol. xxi. (Section of Botany).—Besides the proceedings, the volume contains the first part of an excellent monograph, by M. Aggeenko, on the flora of Crimea, being a description of the botanical geography of the peninsula. The orography and hydrography of Crimea, and its various soils, are shortly described, as also its climate. The periodical phenomena of blooming and fruit-bearing are next dealt with. The following chapter is devoted to the analysis of previous exploration, and the remainder of the work is given to the description of the character of vegetation in the Steppes of Crimea, on the northern slope of the highlands, the flat summits of the Yaila highlands, and especially the southern slope. The influence of man and of the fauna on vegetation is briefly treated, and a new species, *Alyssum rotundatum*, as well as a new variety of Orchids (*Ophrys aranifera*, Hudson, var. *taurica*) are described and figured on plates. A very interesting geo-botanical map of Crimea is given.—A paper on the pigments of Fungi, by A. Nadson, must be rather considered as a preliminary communication, containing many valuable data on the pink, yellow, red, and orange pigments of some fifteen species.—On the crystals in the leaves of the *Anonaceæ* and *Violarieæ*, by Prof. Borodin.

Vol. xxii. (Section of Zoology and Physiology).—Ornithological observations in the middle course of the Amu-daria in the Tcharjui-kelif region, by A. Yaschenko. A list of 161 species of birds and their distribution in various regions (cultivated, mixed, deserts, and mountains) is given, each of the regions being described separately as to its most characteristic birds.—On the hybrids between *Butydes flava* and *Butydes campestris*, by N. Zaroudnoi. — On the embryonal development of *Phyllodromia* (*Blatta*) *Germanica*, by N. Kholodkovsky, being a very elaborate and valuable contribution to comparative embryology. It is the fruit of a four years' laborious research, and is accompanied by five large well-drawn plates.

Bulletin de l'Académie des Sciences de St. Pétersbourg, Nouvelle Série, t. ii., No. 3.—The ephemeris and the approximate elements of the comet of Encke for the year 1891, by O. Backlund (in German). The ephemeris is calculated from July 2 to November 1, 1891, after having taken into account the perturbing influences of Venus, the Earth, Mars, and Jupiter in 1884–88, and Jupiter alone from March 7, 1888, to May 31, 1891.—Additions to the Flora of the Caucasus: i. Two new varieties of *Rhamnus*, by N. Kuznetsoff (in German, with two plates).—On the radiants of the Andromedides, by Th. Bredikhine (in French), with a plate. The meteoric current of November 27, 1872, and 1885 is studied, the former on the ground of the observations of the Brera Observatory at Milan. The positions of the radiants are given on a map, upon which the orbit of the comet of Biela (for 1859) is also traced. The positions of the radiants being taken into account, the author compares the probable elements of the meteoric current with the orbit of the Biela comet. Taking further into account the meteoric currents observed on December 7 and 8 in 1798, 1830, 1838, and 1848, the author concludes that those currents must have belonged to the orbit of the same comet before the severe perturbations it suffered through the influence of Jupiter in 1794.—Observations of 51 double stars, followed by a research into systematic errors, by F. Renz, of Pulkova (in German). The observations and the catalogue based upon them are given.—On some old and new catalogues of stars, by J. Seyboth (in German). Before the printing of Romberg's catalogue a comparison of its data with those of previous catalogues was felt to be necessary. A series of comparative measurements has been undertaken for that purpose, and their results are given in the introduction to Romberg's catalogue. Further comparison is now made with the catalogues of Struve, Argelander, Pulkova (3542 stars), Becker, and Gould, and reduction tables are given.—A new Bacterium, *Nevskia ramosa*, by A. Famintzin (in German), with a plate. This strange organism, so widely different from all known Bacteria, but not unlike to Metchnikoff's *Pasteuria ramosa*, consists of a jelly-like ramified growth, the Bacteria cells appearing upon the ends of the branches. It forms colonies similar to those formed by some Algæ and Infusoria (*Urococcus*, *Gomphonema*, *Epistylis*).—On the libration of Hyperion, by H. Struve (in French). The last years' observations of this satellite of Saturn, which have been made with the aid of the great Pulkova refractor, having disclosed considerable discrepancies from the ephemerides calculated by Mr. Marth, the Pulkova astronomer tried to explain them—and succeeded to a great extent—by a libration which has a short period of 641 days, and an amplitude of 9° in the average longitude.—Revision of the Hymenopteres of the Zoological Museum of the Academy, by A. Semenoff: i. Genus *Cleptes* (in Latin). The following new species are described: *Cleptes flammifer*, *obsoletus*, *Buyssonis*, and *Mocsarii*; ii. Genus *Abia* (new species): *A. symballophthalma*.—New Gentianæ from Asia, by N. Kuznetsoff. The following new species, some of which had already been recog nized as new by Maximowicz, are described: *Gentiana Maximowiczi, leucomelæna, purpurata, siphonantha, Regeli, glomerata*, and *G. Kuroo*, var. *brevidens*. They are from Central Asia, North China, and Mongolia.—Report of the International Meteorological and Polar Conferences, and the International Committee of Weights and Measures, by H. Wild. No. 4: Remarks on Mr. Kock's work, "Comicorum Atticorum fragmenta" (in German).

LONDON.

Royal Society, May 5.—"Transmission of Sunlight through the Earth's Atmosphere. Part II. Scattering at Different Altitudes." By Captain W. de W. Abney, C.B., D.C.L., F.R.S.

In this paper the results of observations made by exposing platinotype paper are recorded, and it is shown that the total intensity of light as thus registered is the same as if observations had been made on a ray of λ 4240 alone. The observations were made at altitudes varying from sea-level to 12,000 feet in different countries, at different times of the year, and during four to five years. The instrument in which the exposures were made is described, as also the method of deriving the intensity of light from the developed prints. The results of these observations agree closely with those obtained by the measures of the spectrum which was described in Part I. of this subject. The value of k in the formula (1) $I' = \epsilon^{-k\lambda^{-4}x}$ (from which can be calculated the loss of intensity of a ray of any particular wave-length) was found to be 0·00146 at sea-level. It was also found that k apparently varied as h^2, h being the barometric pressure. A table is attached, showing the value of the transmitted light in the formula (2) $I' = Iax$, where a is a constant and x the air thickness in terms of the vertical thickness, μ being the formula $I' = I\epsilon^{-\mu x}$, from which (1) and (2) are both shown to be derived.

Linnean Society, April 21.—Prof. Stewart, President, in the chair.—An example of an Australian bird (*Gymnorhina*), which had lately been shot near Tor Abbey, Devonshire, after being observed all the winter, and which had doubtless escaped from confinement, was exhibited on behalf of Mr. W. Else, Curator of the Torquay Museum.—On behalf of Mr. Charles Head, of Scarborough, two specimens of the Whiskered Bat (*Vespertilio mystacinus*) taken in that neighbourhood were exhibited.—Mr. W. B. Hemsley, F.R.S., read a paper entitled "Observations on a Botanical Collection made by Mr. A. E. Pratt in Western China, with descriptions of some new Chinese plants from various collections." Mr. Pratt travelled in 1889–90 in Western China, close on the borders of Eastern Tibet, and though chiefly in search of zoological specimens, he fortunately secured the services of a native who had been trained to dry plants by Dr. Henry, the result being that he was enabled to bring home a very interesting botanical collection. The plants were obtained chiefly at elevations of 9000 to 13,500 feet, in the neighbourhood of Tat-sien-lu, a frontier town situated in about 30° N. lat. and 102° 15′ E. long.; and although Mr. Hemsley reported that he had not finished working out the collection, he estimated that it contained about 500 species, of which perhaps 150 species were new to science. The paper was criticized by Mr. C. B. Clarke, who remarked that the mountain ranges of Western China seemed to abound in showy herbaceous plants, rivalling in this respect the richest districts of the Himalayan region, of which, in fact, it is a continuation.—Mr. H. M. Bernard then gave an abstract of a paper on the relation of the Acaridæ to the Arachnida, in which he argued that the former were fixed larval forms of the latter; though he found a difficulty in dealing with the segmentation, this being so profoundly modified and in some cases lost. The paper was criticized by Mr. A. D. Michael, Mr. Breeze, and Prof. G. B. Howes, all of whom, while testifying to the ingenuity of Mr. Bernard's reasoning, considered that there was hardly as yet sufficient evidence to justify the acceptance of his conclusions.

May 5.—Prof. Stewart, President, in the chair.—On behalf of Mr. Holt, Prof. G. B. Howes exhibited and made remarks on a very interesting collection of the metamorphosing larvæ of flat-fish.—Mr. Curtis showed a photograph of sections of the Silver and Douglas firs, illustrating the relative rate of growth in trees of the same age growing in the same soil and under similar conditions in all respects, the diameter of the one (*A. Douglasii*) being nearly double that of the other.—Mr. George Murray exhibited spirit specimens of *Ascothamnion intricatum*, an organism described as a siphoneous Alga, but ascertained to be identical with an animal—namely, *Zoobotryon pellucidum*, Ehrenberg. He also exhibited two specimens of a palm (*Thrinax Morrisii*, Wright), peculiar to Anguilla in the Leeward Islands, and made some remarks as to the results of the recent cryptogamic collections made by Mr. W. R. Elliott for the West India Committee.—Mr. Holmes exhibited and made some observations on an abnormal development of the calyx in a primrose.—The President exhibited and explained a collection of Lepidoptera containing several examples of mimicry between protected forms.—On behalf of Dr. J. Müller, Mr. Thiselton Dyer communicated a paper entitled "Lichenes Epiphylli Spruceani."—Mr. W. F. Kirby gave an abstract of a paper on the family *Saturnidæ*, with descriptions of new species in the British Museum.—In the absence of the author, Mr. W. Percy Sladen read a paper by the Rev. Hilderic Friend, entitled "Observations on British Earthworms."—The President announced that the anniversary meeting of the Society would be held on May 24, at 3 p.m.

Royal Microscopical Society, April 20.—The President, Dr. R. Braithwaite, in the chair.—Mr. A. W. Bennett called attention to some slides received from Prof. D. P. Penhallow, of Montreal, who sent them to illustrate an improved method of labelling. Instead of writing upon the usual paper label, he writes directly upon the glass, and covers the writing afterwards with a thin coating of Canada balsam, which makes it permanent.—Prof. F. Jeffrey Bell said that, the Council having concluded the negotiations with their landlords, the rooms of the Society would now be open for the use of the Fellows every Wednesday evening from 6 to 10 p.m., from November till June. This order would take effect at once.—Mr. F. Chapman's paper onthe Foraminifera of the Gault of Folkestone was read.—Surgeon P. W. Bassett-Smith's paper on the deep-sea deposits of the Eastern Archipelago was read by Prof. Bell. H.M.S. *Penguin*, to which Surgeon Bassett-Smith was attached, made a passage during the latter part of 1891 from Port Darwin, North-west Australia, through the Arafora, Banda, Celebes, Sulu, and China seas to Hong Kong. A continuous and close line of soundings was taken through the whole passage, the deepest water being 2880 fathoms in the Banda Sea. In almost every instance specimens of the bottom were obtained. They consisted mostly of "green muds," with a few "blue" and "brown muds" in the deeper parts. The definition of "green mud" is a very wide one; broadly it may be divided into that in which calcareous organisms, chiefly Globigerina, predominate, and that in which the tests of Radiolarians have taken their place; this latter condition was almost always present in "brown muds." The inorganic materials were either fine quartz sand in the deeper and more distant positions, or, as the coast was approached, argillaceous matter together with sponge spicules and small shells. In places the material was typically volcanic, as in the upper part of the Banda Sea, among the Moluccas, and on the coast of Luzon. Only two specimens of pure Globigerina ooze were obtained, both being in the Molucca passage, one in 1885 fathoms and the other in 197 fathoms. It would seem that in the deeper parts of the seas the bottoms consist of Radiolarian muds, and the shallower parts of Globigerina muds, the line being roughly drawn at 1500 fathoms. In almost every case over 2000 fathoms the siliceous organisms were undoubtedly most abundant.—A note was read from Dr. E. Giltay on the use of the camera lucida in drawing Bacteria, in which he recommended the illumination of the drawing by a powerful lamp, and the testing of the drawing by a slight change in the position of the paper, so as to compare side by side the drawing made and the camera lucida outline. Dr. Giltay stated he had succeeded in drawing objects magnified 2500 times. Mr. A. D. Michael thought the method of comparison would be likely to produce distortion.—Prof. Bell said a note had been received from Mr. J. C. Wright on some rotifers which he had found attached to a newt. The accompanying drawings did not render it sufficiently clear that what he had found were really rotifers, and he suggested they were Vorticellæ. —A note from Mr. W. M. Osmond was also read, descriptive of a new cheap photomicrographic stand. Dr. W. H. Dallinger thought that though it might be useful for low-power work, he doubted if it would be of value for high or even moderate powers. He should be afraid that there would be too much vibration. Mr. C. L. Curties said he should be sorry to use it for anything beyond a half-inch objective.

Geological Society, April 27.—Prof. J. W. Judd, F.R.S., Vice-President, in the chair.—The Chairman announced that the Organizing Committee of the International Geological Congress have arranged to convene the sixth meeting of the Congress at Zürich, about the commencement of September 1894. Any communications should for the present be addressed to Prof. E. Renevier, University, Lausanne.—Prof. W. C. Williamson, F.R.S., exhibited the following specimens: slab of Carboniferous Limestone from Bolland, illustrating the passage of a foraminiferal ooze into crystalline calcite; *Asteropecten Orion*, Forbes, from the Kellaways rock, near Pickering, Yorkshire; and made the following remarks:—The specimen before me is a slab of Carboniferous Limestone from the Bolland district of West Yorkshire. In its centre is a magnificent section of a large Nautilus—beautiful as a fossil, but still more important because of what it teaches. Its large terminal chamber is filled with foraminiferal ooze, the component objects of which are almost as perfect as when the organisms were living. The surrounding limestone is chiefly in an amorphous state; but it contains innumerable evidences that it also consists of foraminiferal ooze, largely reduced to the amorphous state by the agency of carbonic acid, now known to be so abundant in the depths of the ocean. The action of this acid upon the minute calcareous shells necessarily converted the water into a solution of carbonate of lime. In this state it percolated by osmosis through the shell of the Nautilus, penetrating its closed chambers, which it gradually filled with calcareous spar. The specimen is thus an epitome, within its limited area, of what has taken place on a gigantic scale in the deep sea. We have here first the organic mass, next its conversion into amorphous limestone, and lastly the production of the crystalline state of the same, so frequently seen filling the interiors of fossils. The second object is the original type-specimen of Forbes's *Asteropecten Orion*, from a sandstone bed of the Kellaways rock in the neighbourhood of Pickering, in Yorkshire. This starfish had lived upon and became buried in a sandy matrix which contained no lime. When the rock was split open, the space originally occupied by the starfish was hollow; the sand contained no soluble material, like that which filled the chambers of the Nautilus. But in the lowest beds of the Coralline Oolite at Filey Brigg, on the Yorkshire coast, we long ago found another species of starfish closely allied to the Pickering species. This was embedded in calcareous stone, which had once in all probability been foraminiferal ooze, and the processes which filled the chambers of the Nautilus also filled the cavity left by the decay of the starfish with crystalline carbonate of lime. These specimens, studied collectively, illustrate two of the most important and common of the processes by which the mineralization of fossil remains has been effected.—The following communications were read:—Notes on the geology of the Northern Etbai or Eastern Desert of Egypt, with an account of the emerald mines, by Ernest A. Floyer. The principal feature in the district is a long ridge of igneous upthrust running north north-west and south-south-east, in which porphyry rises into lofty peaks, whilst the lower parts are formed of granites and sedimentary rocks. To the west of the watershed, sedimentary rocks occur dipping slightly to the west. The following succession of rocks in descending order is given by the author: limestone, sandstone, clay, "cataract"-rock (corresponding to the *Stock-granit* of Walther), and compact hard granite. The sedimentary rocks are frequently metamorphosed, and the author states that every stage of metamorphism is shown, from sandstone to compact green granite. The blue clay shows various kinds of metamorphism, and forms the pistachio-breccia containing topazes, and the mica-schist, mica-slate, and talcose blue clay of the mass of Zabbara containing emeralds. The author discusses certain theoretical questions, and considers that the erosion of the valleys does not indicate the existence of a greater rainfall than the present one. He concludes by giving an account of the emerald mines. The reading of this paper was followed by a discussion, in which Prof. Hull, Prof. Le Neve Foster, Mr. Rudler, Mr. J. W. Gregory, and Dr. Blanford took part.—The rise and fall of Lake Tanganyika, by Alex. Carson (communicated by R. Kidston). In this paper attention is called to certain recorded discrepancies concerning the discharge of Tanganyika by the Lukuja. It is suggested that the rise of the lake is due to the blocking-up of the river by vegetation, assisted by silting during the first rains, whilst the fall is produced by the destruction of the barrier formed in this manner.

Zoological Society, May 3.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April, 1892, and called attention to a finely-marked Owl (*Pseudoscops grammicus*) from Jamaica, presented by the Jamaica Institute, being the first example of this Owl that has reached the Society.—Mr. Sclater exhibited and made remarks on a fine specimen of the egg of *Æpyornis*, the extinct giant bird of Madagascar, obtained from Southern Madagascar, and brought to this country by Mr. Pickersgill, H.B.M. Vice-Consul at Antananarivo.—Mr. Oldfield Thomas read a paper on the probable identity of certain specimens formerly in the Lidth de Jeude collection, and now in the British Museum, with those figured by Albert Seba in his "Thesaurus" of 1734.—Mr. F. E. Beddard read some notes on various species of aquatic Oligochætous Worms that he had lately had an opportunity of examining. Amongst these was a new form allied to *Acanthodrilus* from the saline waters of the Pilcomayo, discovered by Mr. Graham Kerr during the Pilcomayo expedition.—Dr. Hans Gadow read a paper on the systematic position of *Notoryctes typhlops*, the newly-discovered Mammal of Central Australia, and came to the conclusion that this anomalous form should stand as a distinct family of Polyprotodont Marsupials, allied to the Dasyuridæ and the Peramelidæ.—A communication was read from Captain H. G. C. Swayne, R.E., containing field-notes on the Antelopes of Northern Somali-land. —Mr. W. Schaus read the second portion of his descriptions of new species of Lepidoptera Heterocera from Brazil, Mexico, and Peru.—Mr. W. L. Sclater read some notes on certain specimens of Frogs in the Indian Museum, Calcutta, and gave descriptions of several new species based upon some of these specimens.

Entomological Society, May 11.—Frederick DuCane Godman, F.R.S., President, in the chair.—The President announced the death, on May 4, of Dr. C. A. Dohrn, of Stettin, one of the ten Honorary Fellows of the Society. Mr. Stainton, F.R.S., expressed regret at the death of Dr. Dohrn, whom he had known for a great number of years, and commented upon his work and personal qualities.—Dr. D. Sharp, F.R.S., exhibited drawings of the eggs of a species of Hemiptera, in illustration of a paper read by him before the Society; and also a specimen of a mosquito from the Amazon district, with the body, legs, and palpi furnished with scales as in Micro-Lepidoptera.—The Rev. Canon Fowler, on behalf of Mrs. Venables, of Lincoln, exhibited cocoons of a species of *Bombyx* from Chota Nagpur, India; also the larvæ-cases of a species of Psychidæ, *Cholia crameri*, from Poona, India; and a curious case, apparently of another species of Psychidæ, from the island of Likoma, Lake Nyassa.—Mr. F. W. Frohawk, on behalf of the Hon. Walter Rothschild, exhibited a specimen of *Pseudacræa miraculosa* mimicking *Danais chrysippus*; also a specimen of the mimic of the latter —*Diadema misippus*—and read notes on the subject.—Mr. C. G. Barrett exhibited, and commented on, a long series of specimens of *Melitæa aurinia* (*artemis*) from Hampshire, Pembrokeshire, Cumberland, and other parts of the United Kingdom; also a long and varied series of *Coremia fluctuata*.—Mr. H. Goss exhibited, for Mr. W. Borrer, Jun., of Hurstpierpoint, a photograph of a portion of a nest of *Vespa vulgaris* which had been built with the object of concealing the entrance thereto and protecting the whole nest from observation. He also read notes on the subject, which had been communicated to him by Mr. Borrer.

—The Hon. Walter Rothschild communicated a paper entitled "Notes on a collection of Lepidoptera made by Mr. William Doherty in Southern Celebes during August and September, 1891." He also sent for examination the types of the new species described therein.—Dr. Sharp read a paper entitled "On the eggs of an Hemipterous Insect of the family *Reduviidæ*. Mr. McLachlan, F.R.S., Mr. Poulton, F.R.S., and Mr. Hampson made some remarks on the subject.

Mathematical Society, May 12.—Prof. Greenhill, F.R.S., President, in the chair.—The following communications were made:—A Newtonian fragment on centripetal forces, by Mr. W. W. Rouse Ball. The demonstrations given by Newton in his "Principia" are geometrical, though there is little doubt that in establishing the truth of some of his results he used fluxions (cf. the "Commercium Epistolium," Rigaud's "Essay on the first publication of the 'Principia,'" and Brewster's "Life of Newton"). To his contemporaries the language and methods of geometry were familiar, while to most of them the calculus was unknown; hence it was natural and reasonable that the proofs should be presented in a geometrical form. It is probable that the fluxional analysis by which a result was obtained was generally thrown aside as soon as a synthetic geometrical proof had been found; apparently the only proposition in the book of which Newton's fluxional demonstration has been published is his determination of the form of the solid of least resistance, of which the result alone was given in Book ii., Scholium to Prop. 35 (first edition). Among the numerous sheets of rough work and calculations which are preserved in the Portsmouth collection is a fragment on the law of centripetal force under which any orbit, and particularly a parabola of any order, can be described. The theorem to which the analysis leads is so inconvenient of application as to be practically useless, and probably for that reason was not inserted in the "Principia." Such interest as it possesses lies rather in its illustrating the way in which Newton arrived at the law given (in the paper) for the description of any parabola under a central force. The date of the fragment is put "about the year 1694," when we know that Newton was engaged in revising the first edition of the "Principia."—On an operator that produces all the covariants and invariants of any system of quantics, by Dr. W. E. Story.—Applications of a theory of permutations in circular procession to the theory of numbers, by Major MacMahon, F.R.S.

Oxford.

University Junior Scientific Club, March 18.—Mr. J. A. Gardner, Magdalen College, President, in the chair.—A paper was read by Mr. J. E. Marsh, Balliol College, on variations in the rotatory power of turpentine oil. This was chiefly given up to the consideration of the probable explanation of the phenomenon. The experiments were described at length in the Journal of the Chemical Society some months back.—Mr. T. H. Butler, of Corpus Christi College, read a paper on poisons, chiefly in relation to their physiological action.—Mr. H. Balfour, of Trinity College, exhibited a whaling cross-bow from Greenland.—Mr. F. Britten, of Christ Church, exhibited a specimen of incrustation.

March 30.—Mr. J. A. Gardner, President, in the chair.—Mr. E. B. Poulton, F.R.S., read a paper on a further investigation of the degenerate scales of Lepidoptera with transparent wings, which was illustrated by the magic lantern.—Mr. O. V. Darbishire, Balliol College, read a note on karyokinesis, illustrated by microscopical preparations.—A note was read by Mr. R. S. Hughes, Jesus College, on the action of dried hydrogen sulphide on magnesia.

Dublin.

Royal Dublin Society, April 20.—Sir Robert Ball, F.R.S., in the chair.—The following communications were made:—On a new mercury-glycerine barometer, by Dr. J. Joly. This barometer has the full range of the glycerine barometer. The total length of the tube is, however, only 250 cms. about. This result is attained by weighting the glycerine in the tube by a column of mercury 67 cms. in length. By means of a float in the mercury which pulls a disk, loosely fitting the tube, against the base of the column, this is kept from breaking, and falling down through the glycerine. In a uniform tube this column remains of invariable length and moves up and down with the glycerine. The balance of the atmospheric pressure is equilibrated by glycerine drawn from a bath of glycerine. Owing to the short length of tubing traversed by the viscous liquid, the instrument is probably more prompt than the full length glycerine barometer. On the other hand, there appears to be a very slow ascent of the glycerine past the mercury, which will probably necessitate the resetting of the instrument at intervals.—Mr. J. R. Wigham read a paper explanatory of the new "giant" lighthouse lens, the largest ever made, which he exhibited to the meeting. It was constructed for him by Messrs. Barbier and Co., of Paris. Its focal distance is 2 metres, and its axial intensity equal to 800,000 candles. The beam which this lens, in triform, in conjunction with Mr. Wigham's new "intensity" burner, is capable of transmitting to the mariner, has more than five times the power of that of Tory Island, the largest lighthouse light in the world, and is much more efficacious in penetrating fog than the most powerful electric light. —Dr. G. Johnstone Stoney, F.R.S., read a paper on the cause of the absence of hydrogen from the earth's atmosphere, and of water and air from the moon. In this communication reference is made to the conditions that determine the height of an atmosphere upon any celestial body. These had been announced by the author in a paper "On the Physical Constitution of the Sun and Stars," printed in the Proceedings of the Royal Society for 1868; and in the present paper it is pointed out that the same method of investigation shows that under certain circumstances some of the constituents of an atmosphere may, molecule by molecule, wander off into space. This event occurs with more readiness—(1) the lower the mass of the molecules of the gas; (2) the feebler the attraction downwards at the boundary of the atmosphere; (3) the higher the temperature at the boundary of the atmosphere. By investigating the conditions that prevail on the earth and moon, it is shown that free hydrogen could not remain a constituent of the earth's atmosphere; and that no free oxygen, nitrogen, or the vapour of water, could remain on the moon. Hence, even if there were no oxygen present, the earth's atmosphere could not retain free hydrogen; and on the moon there is now neither atmosphere, such as we know it, nor water, nor ice. It follows from the investigation that space must be peopled with vast numbers of wandering gaseous molecules, especially of the lighter gases, and that these tend ultimately to settle down upon such of the more massive bodies of the universe as are sufficiently dense to exercise a powerful attraction at their surface. Finally, the investigation indicates conditions which must be fulfilled by any "nebular hypothesis" in order that it may be admissible.—A list of Irish Rotifers, with descriptions of twenty-five new species, by Miss Glascott, was communicated by Prof. A. C. Haddon.

Paris.

Academy of Sciences, May 9.—M. d'Abbadie in the chair.—Photographs of solar prominences taken by M. Deslandres at Paris Observatory, by M. Mouchez. This is a brief statement of the work that is being done at Paris on the dimensions and velocities of solar prominences. By the methods employed the radial velocity can be determined within about a kilometre per second. Some of the photographs obtained were presented by M. l'Amiral Mouchez to the Academy. It is proposed to make a continuous record of the movements of the solar atmosphere as soon as the necessary funds are obtained.—On the propagation of Hertz oscillations, by M. H. Poincaré.—On residual life and the products of the action of separate tissues of living beings, by MM. A. Gautier and L. Landi. After a healthy animal has been killed, a considerable interval elapses before the death of the tissues. This action after the death of the body as a whole is termed "*la vie residuelle*" by the authors. They have investigated the changes that go on by analyzing flesh freshly killed and otherwise, and comparing the results.—On entire functions of the form $e^{G(x)}$, by M. Hadamard.—A theorem on harmonic functions, by M. G. D. d'Arone.—On the determination of the moment of the torsion couple of a unifilar suspension, by M. C. Limb.—Action of potassium cyanide on ammoniacal copper chloride, by M. E. Fleurent. By heating together in sealed tubes potassium cyanide, cupric chloride, and ammonium chloride, the author has succeeded in forming the compounds, (1) $2Cu_2Cy_2 . AmCy . 2NH_3 . 3H_2O$, forming long blue needles, very unstable; (2) $2CuCy_2 . Cu_2Cy_2 . 2NH_3 . 3H_2O$, green rectangular plates, quite stable in the air.—Sodium trimethylcarbinol:

thermal value of the replacement of H by Na in a tertiary alcohol, by M. de Forcrand.

$C_4H_{10}O$ sol. + Na sol. = H gas + C_4H_9ONa sol. . . . +27·89 cal.

For secondary and primary alcohols the values are respectively +29·75 and +32·00 cal.—Establishment of the fundamental formulæ for the calculation of maximum moments of inertia (of molecules), by M. G. Hinrichs.—The constitution of the hydrocarbon derived from perseïte, by M. L. Maquenne.—The chemical properties and analysis of acetyl fluoride, by M. Maurice Meslans. (See Notes.)—The acid antimonite of pyrocatechol, by M. H. Causse.—Action of organic acids on acetylenic hydrocarbons, by MM. A. Béhal and A. Desgrez.—On the stranding of a whale mentioned in the 113th Olympiad, by M. G. Pouchet.—On the physiological constitution of the tubercles of potatoes in relation to the development of shoots, by M. A. Prunet.—On the old glaciers of the Cordilleras of Chili, by M. A. G. Nogués.—On the genus *Megapleuron*, by M. Léon Vaillant.—On a Dicotyledon found in the Upper Cretaceous on the environs of Sainte-Menehould (Marne), by M. P. Fliche.

AMSTERDAM.

Royal Academy of Sciences. April 29.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Behrens dealt with the microscopic structure of alloys. Crystallization is a common phenomenon in metals. The least crystalline are pure Al, Cu, Ni, when cast without overheating. Rapid cooling has no other effect than to make the crystals of smaller size. Pure Ag does show always crystallization, if properly etched. In alloys crystallization is more easy and perfect than in unalloyed metals. When 1 gr. of Cu, alloyed with 2 mgr. Ag, is melted and slowly cooled, it will be found chequered by minute threads of an alloy rich in silver. All types of structure found in crystalline rocks can be reproduced in alloys. The most common is rectangular wickerwork, less common are isolated clusters of crystals (alloys with few crystals of high melting-point, as in Zn + 10 per cent. Pt, Cu + 10 per cent. Co). Mechanical stress does not destroy the crystalline structure. A fibrous or lamellar structure is set up, corresponding with planes of sliding or shearing in intercrystalline matter, and under heavy stresses partly due to flattening and stretching of crystals. By annealing, alloys of Cu with Ni can be made to crystallize even as soft iron, thereby becoming even brittle.—Mr. Schoute treated of movement in space of *n* dimensions.—Mr. Bakhuis Roozeboom treated of the hydrates of iron perchloride.—Mr. Kapteyn made a communication on the distribution of the stars in space. He has compared the spectral type of stars of different proper motion. For this latter element the list given by Mr. Stumpe in the *Astr. Nachr.*, Nos. 2999–3000, was used; the spectral types were taken from Mr. Pickering's "Draper Catalogue." 476 stars not fainter than 7·0m. were found common to the two catalogues. Together with these, 115 other well-determined stars were used, taken from Bradley's catalogue, whose proper motion according to Auwers's reduction is less than 0·003s. in R.A., and less than 0″·03 in Decl. This material, arranged according to the amount of the proper motion, leads to the following conclusion:—The region of the universe nearest to our planetary system contains nearly exclusively stars of the second type (Pickering's Cl. E–L); with growing distances the number of stars of the first type (Pickering's Cl. A–D), relatively to the number of those of the second type, increases gradually and approximately in inverse ratio with the proper motion (*i.e.* very probably in direct ratio with the distance) in such a way that equality of number is reached at a distance corresponding to a proper motion of 0″·08 or thereabout. At distances still greater, the stars of the first type begin to preponderate, and they are more than twice as numerous as those of the second type at the mean distance of those of Bradley's stars, whose proper motion is insensible. From the differences between visual and photographic magnitudes Mr. Kapteyn shows that analogous results will most probably be found for the southern hemisphere as soon as a catalogue of southern star spectra is published. The investigation further indicates, though far less clearly, for the centre of symmetry of the system, a situation at a certain distance from the sun in the direction of 23 hours of R.A. Lastly, it is demonstrated that, even for distances corresponding to proper motion of 0″·16 to 0″·30, no accumulation of stars towards the plane of the Milky Way is shown; that for distances considerably greater this accumulation cannot be considerable, and that the Milky Way must be attributed therefore to stars at enormous distances.—Mr. Franchimont communicated an experiment used by him in his College during several years to show that the presence of hydriodic acid is necessary for the formation of iodine starch.

GOTTINGEN.

Royal Society of Sciences.—The following papers of scientific interest have appeared in the *Nachrichten* since November 11, 1891:—

November 11, 1891.—E. Riecke and W. Voigt, the piezo-electric constants of quartz and tourmaline.

November 25.—Franz Meyer, on a persistence-theorem for algebraic equations. Starting from the theorem that, for a cubic equation, the sum of the number of real roots for the cubic and its Hessian together is always three, the author finds for any equation of odd order a series of forms such that the sum of the real roots of the equation and these forms together is always the same.—Otto Bürger, preliminary communication on the *Nemertina* of the Gulf of Naples.—Otto Wallach, on certain new hydrocarbons with a ring of carbon-atoms.

December 23.—Alfonso Sella, contribution to our knowledge of the specific heats of minerals.—Frobenius, on potential functions whose Hessian is zero.—Schönflies, remark on Hilbert's theory of algebraic forms.—Alberto Tonelli, remark on the solution of quadratic congruences.—P. Drude and W. Nernst, on fluorescence-effects of stationary light-waves.

January 27, 1892.—Heinrich Burkhardt, the reduction of the twenty-seven lines of a cubic surface to the transformation problem of the hyper-elliptic functions for $p = 2$.—David Hilbert, on the theory of algebraic invariants.—Clemens Hartlaub, on the *Anthomedusæ*.

March 9.—J. Disse, changes in the renal epithelium during secretion.—Kroeker, the dependence of the specific heat of boracite upon the temperature.

MATHEMATICS USED IN PHYSICS.

Einleitung in die Theoretische Physik. Von Victor von Lange. Second Edition, Enlarged and Revised. (Braunschweig: Vieweg, 1891.)

THIS work is intended to give an account of the mathematical processes employed in physical investigations. It is divided into chapters dealing with the various branches of physics, mechanics, gravitation, magnetism, electricity, solids, fluids, gases, light, and heat. It is very difficult in such a book to decide how far to go in mathematical processes, and Herr von Lange has exercised his discretion wisely in this matter. At the other limit of how little to assume known he has certainly not erred in the direction of assuming too much, for he introduces proofs of simple differentiations and integrations when he requires them, which had much better be learnt continuously in an elementary treatise on the calculus. No English student would use a book of this advanced character without some preliminary mathematical training, and it is very doubtful whether anybody picking up the calculus in this haphazard fashion could ever use it in his own investigations; and if it is no use to him for this, would it not be a great saving of time and energy for him to depend on the investigations of others without going through all their work, just as an investigator of magnetic declination need hardly expect to have time to work through the lunar and planetary theories that help in the calculations of the *Nautical Almanac* he uses? A work of this kind is of great service as a concentrated store of information for those who want to study physics, and who have sufficient mathematical ability and training to be able to use the mathematical processes involved; but it cannot successfully compete with special treatises on the elements of solid geometry, differential calculus, &c., as a means of supplying the mathematical training required in order to use these processes.

Some readers may be disposed to doubt whether it is worth while introducing into a work of the scope of this book any elementary dynamics. The subject, however, wastes only a few pages, and it may very well be worth while introducing it in order to avoid references and explanations that might be quite as long. His discussion of the nature of mass is hardly satisfactory without a description of apparatus and methods of experimenting, but, so far as it goes, is fairly sound. He does not point out with sufficient clearness where definition ends and observation comes in. These are, however, really physical questions, with which a mathematical work might very well dispense. In discussing the rotation of a solid subject to forces, he bases his investigation on Airy's mathematical tracts, but he does not safeguard himself with all the provisos Airy so carefully introduces; and in consequence there are many pitfalls, carefully hidden. The method is based upon supposing the body given a series of blows, and appears on the face of it to be purely kinematical. It is on the other hand evident that, in general, dynamical questions, such as the centrifugal acceleration introduced when the axis of rotation is not a principal one, must come into consideration when discussing the forces that must be applied to a real body in order to make it move in a given way. A student of this investigation would be puzzled to understand how it happens that a solid sphere, when rotating round an axis and given a blow, begins to rotate round a new axis, new both inside the sphere, and in space, while a gyroscope takes up a wobble. It is possible by a series of blows given to a sphere to cause its axis of rotation to move round in space while preserving its position in the sphere, but a series of blows in general would not produce this result. The kinematic investigation of rotation of a solid round an axis accompanied by an angular acceleration round a rectangular axis is an interesting geometrical question, but must be carefully distinguished from the dynamical question of what forces must be applied to a real solid in order to produce this motion, and these two different questions not being sufficiently clearly distinguished make the investigation unsatisfactory. In connection with the motion of a solid, it is to be regretted that a short account of the theory of screws was not included.

Under gravitation at one place, there is a full account of free fall, pendulums, balances, bifilar suspensions, torsion balance, &c. Then he proceeds to questions depending on gravitation at different places, the figure of the earth, the constant of gravitation. Here he mentions Foucault's pendulum, and notices that the elementary investigation is insufficient, without, however, giving more than the result of the complete investigation, not even explaining why the elementary investigation fails, owing to the precessional motion of the axes of the ellipse in which the bob of the pendulum necessarily moves, and which becomes comparable with the motion looked for, unless the amplitude be very small and the suspending thread very long. This chapter concludes with an account of the theorems connected with forces varying inversely as the square of the distance. It is doubtful whether it would not have been better to deal with this subject in the first place from the hydrodynamical point of view. Such theorems as that the flow is equal across every section of a tube of flow, and its numerous consequences, such as that equal quantities of electricity exist at the ends of a tube of force, that the total normal force over any surface is equal to 4π times the quantity of electricity within, &c., are all intuitively evident in hydrodynamics, and it is well to call a student's attention to the way in which he can safely argue from the familiar to the unfamiliar.

The chapter on magnetism is very complete, though the action of two magnets on one another is done in a fearfully long-winded way; and in the account of the determination of magnetic declination the spherical trigonometry required in order to calculate the azimuth of the terrestrial meridian from the astronomical observations is not given. It would also appear as if the determination of variations of dip by means of an induction vertical force magnetometer were quite a different thing from determinations of the variation of vertical force by means of a balance magnetometer. Magnetic induction is the usual mathematical investigation of simple cases where the permeability is assumed constant. An edition dated 1891 might have included some of the mathematics of hysteresis.

Electrostatics is treated as fully as it should be, though perhaps a single chapter on the law of the inverse square, containing most of the theorems required in magnetism and electricity, would have given a sounder view of the mathematics involved. It was hardly to be expected that a mathematician should avoid the temptation of describing Mossotti's theory of dielectrics without a warning that it can hardly be complete, and in consequence gives the electrical displacement as

$$\frac{K-1}{4\pi}$$

instead of $\frac{K}{4\pi}$ times the electrical force, thus making the displacement zero in a vacuum, and justifying this by saying that the results differ very little, while it would really overturn the whole electro-magnetic theory of light. This same overturning is calmly got over when the electro-magnetic theory of light is considered further on by a reference to this place, and this very remarkable statement that $K-1$ differs but little from K. There seems to be some confusion, arising from the fact that in electro-magnetic measure K is nearly 10^{21}, but such a muddle is inexcusable. He further on gives the theory of penetration of electric force into conductors, without referring back to an investigation he has previously given of the concentration of alternating currents on the surface of a wire, not appearing to appreciate that they are the same. He also actually explains wave propagation in dielectrics by induction from layer to layer because the inducing force is *very small* initially at a distance. He has not learnt the A B C of action by means of a medium, but is still hampered by the dry bones of theories of action at a distance. In consequence of this, his investigation of the magnetic action of electric currents is all bristling with the action of elements upon one another, and little or no attention given to the energy stored in the medium, or how it goes from place to place.

The chapter on solids begins with some rather doubtful physical paragraphs that are out of place in a mathematical work. Is it sound to call heat a force (*Kraft*) that holds the particles of bodies asunder? Is it sound to say that the difference between solids and liquids is the difficulty of separating the parts of the former, when it is known that it often takes hundreds of pounds per square inch to separate the parts of a liquid from one another, and when it is the resistance of the material to shear that he really uses as the characteristic of solids? That mistake of making the difficulty of separation and not the difficulty of shearing the characteristic of solids seems quite common: it occurs in many books. The mathematical theory of elasticity is given in the usual analytical way, and applied to some of the simpler cases of bending, &c. Periodic motion is then introduced, and the more important cases of wave motion and vibrations of solids considered. In the consideration of torsion he omits to give any warning as to difficulties arising in the case of non-cylindrical prisms. The chapter concludes with an investigation of the impacts of solid spheres in a manner that brings it into connection with the kinetic theory of gases.

The chapters on liquids and gases are fairly complete. There is an interesting numerical calculation of the height of a statical tide: this is an example of how complete and varied are the physical questions of which the mathematics is given by Herr von Lange. The elementary kinetic theory of gases is given, but without any discussion of the distribution of velocities amongst the molecules. Van der Waals's modification of the simple gaseous laws is discussed, and along with it the theory of cubic equations is given in a rather skimpy form—an example of how difficult it is to teach the higher physical mathematics in a way that applies to the particular case in hand, except by teaching the part of the higher mathematics involved from a wider point of view than the particular solution requires.

The chapter on light is hardly so full as such an important subject demands. Diffraction is run through, but the absence of bands inside a shadow is not discussed, and the theory of definition in telescopes is separated from the same question in microscopes in a very unscientific way. There is a lot of reflection theory, and a paragraph on the direction of the vibration relative to the plane of polarization; but no notice is taken of the theory of the blue sky, nor of the electro-magnetic method of determination, nor of Wiener's proof that it is the electric force which acts on silver salts, and is consequently the one probably effective in most chemical actions, and therefore in irritating the retina. It is possible, however that iron salts may be acted on by the magnetic force.

The last chapter is on conduction of heat and on the mechanical theory of heat. The first part is an account of the simpler parts of Fourier, as any book on conduction of heat must be, and the latter is a good account of thermodynamics. It is to be regretted that he does not give some mechanical illustrations of temperature, though a discussion of the nature of temperature would have been out of place. The chapter concludes with a variety of applications of thermodynamics to such questions as the relations of electromotive force, compressibility, and surface tension, to temperature, as well as the usual one, vapour pressure. It is much easier to point out defects than adequately to describe excellences. It must not therefore be concluded from the fact that much of this review is concerned with the former that the defects preponderate over the excellences of Herr von Lange's work. On the contrary, the work is full of excellences. The way in which physics and mathematics are tending to grow each purer—one in the direction of mathematical abstractions, complexes, matrices, and such like; the other in the direction of experimental methods, accuracy, phenomena, and such like—makes it daily more important for physical investigators especially to have by them a convenient *résumé* of those parts of mathematics that are most often useful to them in their investigations, and this has been ably supplied by Herr von Lange.

PHASES OF ANIMAL LIFE.

Phases of Animal Life, Past and Present. By R. Lydekker, B.A. (Cantab.). (London: Longmans and Co., 1892.)

THE sixteen essays which make up the volume are reprints, with a few alterations, of articles originally published in *Knowledge.* "They are intended," the author tells us, "to illustrate in a popular manner a few of the various modes in which animals—especially vertebrates—are adapted to similar conditions; and also to demonstrate some of the more remarkable types of structure obtaining among the higher vertebrates."

The subject is one upon which Mr. Lydekker is well qualified to write; this is alone a decided recommendation to the book. As a rule, the writing of "popular" books and magazine articles is done by persons who have no special knowledge of the matters of which they treat, and the result of this is not at all gratifying to instructed readers. Mr. Lydekker recognizes the fact that it is impossible to write upon zoology without using plenty of technical terms. When such terms are used they are introduced without any apologies. There are some authors who have the habit of invariably interpolating an apologetic remark in brackets whenever an unusually lengthy word is used. This practice is not at all humorous; and, besides, it is insulting to the intelligence of the reader. Anyone who is likely to read an article upon zoology is perfectly well able to take care of himself when he meets with a strictly technical explanation of some fact. Mr. Lydekker is therefore, in our opinion, quite right in speaking of "Condyles," "Dinosaurs," "Iguanodons," &c., with perfect freedom. Sometimes, however, he goes out of his way to invent or borrow an English equivalent for a scientific name; thus the Ichthyosaurus is always referred to as a "fish-lizard." It seems to us that if there be any fossil creature whose name is absolutely without need of translation it is the Ichthyosaurus; we cannot remember the time when this name was unfamiliar to us; besides, to speak of these reptiles as "fish-lizards" implies that they are intermediate between fishes and lizards, which is by no means the case. It would have been in every way much more reasonable if Mr. Lydekker had spoken of the Dinosaurs as "bird-lizards."

The chapter dealing with these same Dinosaurs is perhaps the most interesting. The information which is given must be newer to the general reader. There is a figure of one of the splendid skeletons of the Iguanodon recently unearthed in Belgium, and now on view in the Brussels Museum; the reproduction of the plate illustrating M. Dollo's memoir upon these remains is not, however, very good; it is difficult to distinguish the numerous small bones which lie along the vertebral column, and which are an indication of the immense development of the tendons of the muscles used to move the powerful tail of the reptile. M. Dollo thought that the Iguanodon lived principally in marshes swimming with the aid of the tail, and only occasionally coming forth to browse upon shrubs on the dry land.

There is naturally a chapter upon the Monotremes. Quite close to the beginning of the chapter it is stated that "within the last few years" these Mammals have been discovered to be oviparous, like reptiles and birds. Mr. Lydekker's book deals mainly with extinct forms of life, and he must have forgotten that in this chapter he was dealing with historical and not with geological time. It is surely unnecessary to remind the author that the oviparity of the Monotremata is not a discovery of the last few years; the *re*-discovery by Mr. Caldwell of this remarkable fact strikingly shows how an important point of this kind may be utterly forgotten. The history of the whole question has been the subject of an interesting article in this journal by Prof. Baldwin Spencer, which appeared two or three years ago.

OUR BOOK SHELF.

Silk Dyeing, Printing, and Finishing. By George H. Hurst, F.C.S. (London: George Bell and Sons, 1892.)

PUBLISHED information connected with the application of colouring matters to silk is somewhat limited, and for the most part scattered throughout the various pamphlets issued by coal-tar colour manufacturers, the periodicals devoted to dyeing, &c.

The present publication is therefore very acceptable, since it brings together, in a convenient and useful form, much of this diffused information, and constitutes one of the well-known series of technological hand-books edited by Sir H. Trueman Wood, Secretary of the Society of Arts.

The author, Mr. Hurst, has here rewritten and brought up to date his articles on the subject of silk-dyeing which appeared during 1889 in the pages of the *Dyer and Calico Printer*, and has added chapters on silk printing and finishing, and on the testing of dyed silks.

The language and style of the book are clear and explicit, and it has evidently been written with distinctly practical aims, so numerous are the working details given throughout the work.

The opening chapter contains an account of the origin, structure, composition, and properties of the most important varieties of silk, followed by one on the preliminary operations of "boiling-off" and bleaching. Special chapters are devoted to the dyeing of blacks, fancy colours, and mixed fabrics. The concluding chapters deal with silk printing, the machinery used in dyeing and finishing, and the examination and assaying of raw and dyed silk.

Some 170 selected and also original recipes, together with 66 dyed patterns of yarn and cloth, appear as an appendix. Altogether the author has succeeded in compressing into a somewhat limited space of about 230 pages, a considerable amount of useful practical information.

In the body of the work, containing numerous technical details of dyeing, explanations of the principles underlying the different processes involved are here and there interspersed, so that the volume may be recommended as a handy book of reference not only for the practical dyer and his apprentice, but also for the student and teacher in technical schools where silk dyeing is taught.

Phycological Memoirs. Edited by Geo. Murray, F.R.S.E., F.L.S. Part I. (London: Dulau and Co., 1892.)

THE establishment of this new serial is an indication of the increased attention given in this country during recent years to the study of Algæ, whether marine or fresh-water. It is intended to form a medium for the publication of the results of researches on Algæ carried on in the Department of Botany at the British Museum, and for making known the treasures of the Museum; and the present number is full of promise of valuable additions to our phycological literature. The place of honour is given to a paper by Miss Margaret O. Mitchell and Miss Frances G. Whitting on *Splachnidium rugosum*, a well-known seaweed of the Southern Seas, hitherto included under the *Fucaceæ*, but which the authors regard as a new type of Algæ occupying possibly an intermediate position between the *Fucaceæ* and the *Laminariaceæ*. For reasons which certainly seem cogent, they are of opinion that the reproductive organs contained in the conceptacles are not sexual oogones and antherids homologous to those of the Fucaceæ, but non-sexual sporanges containing zoospores similar to those of the *Laminariaceæ*. Mr. E. A. L. Batters describes an interesting new genus of perforating marine Algæ, *Conchocelis*, belonging to the order *Porphyraceæ*, which forms pink stains on empty shells, especially those of *Mya truncata* and *Solen vagina*. Miss Ethel S. Barton describes malformations produced in two seaweeds, *Ascophyllum nodosum* and *Desmarestia aculeata*, by the attacks respectively of a new species of Nematode, *Tylenchus fucicolus*, somewhat similar to that which produces the well-known "galls" of *Vaucheria*, and of an undetermined Copepod. The editor himself has two papers, one on a fossil Alga belonging to the genus *Caulerpa*, from the Oolite (Kimmeridge clay of Dorsetshire), a new species, which he names *C. Carruthersii*; and one on the genus of marine Algæ, *Dictyosphæria*, the position of which he retains among the *Valoniaceæ*, near to *Valonia* and *Anadyomene*. The present number is illustrated by eight well-executed plates, most of them coloured. A. W. B.

Live Stock. By Prof. Wrightson. (London: Cassell, 1892.)

THIS is the third of Cassell's series of agricultural text-books, and though hardly equal to other writings of Prof. Wrightson, will be found useful as a reader in elementary classes.

The illustrations are well done, and the text is pretty clear, except perhaps on pp. 52–53, in a paragraph upon the "effect of food on milk." Here it is said that

"The quantity of milk is therefore in some degree dependent on liberal feeding. The quality of the milk is much less easily controlled, and it is doubtful if any special feeding will materially alter the percentage of butter-fats or cream in milk."

Then, at the end of the paragraph we have—

"Watery foods, such as silage, grass, grains, and distillery wash, increase the quantity of milk, but lower the quality, and in town dairies, where a large amount of milk is the principal object, they are much employed."

This paragraph is contradictory and confusing, for Prof. Wrightson himself admits that the quality of milk may be lowered by using watery foods, and we are decidedly of opinion that it may be increased by means of rich, oily foods.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Lord Kelvin's Test Case on the Maxwell-Boltzmann Law.

IN his recent communication to the Royal Society, of a case disproving the Boltzmann law, Lord Kelvin seems to have overlooked an important consideration.

It is well known that in an atmosphere near the earth, under conductive (not convective) equilibrium of temperature, the mean kinetic energy (*i.e.*, the temperature) would be uniform notwithstanding the attraction of the earth, which causes each molecule to move more rapidly at the lower end of its path than at the upper end. This is due to the effect of gravity in sifting out the less rapidly moving particles, preventing them from reaching the upper layers, so that, of the particles in any one layer which reach a higher layer, the great proportion are those which move rapidly in the lower layer. Thus there will be fewer particles in the upper layer, but the mean kinetic energy of a particle will be the same in both.

Applying these considerations to Lord Kelvin's example, it appears that the C particle, when going rapidly, will penetrate a considerable distance into the region of the repulsive force, while, when going slowly, it will only penetrate a short distance. Thus the *duration* of a slow flight might be much shorter than that of a quick one (with a force varying directly as the distance, the durations would be equal). It is quite different with the A particle, which moves uniformly to the end of the tube and back again. The duration of a slow flight will be long and of a quick flight short, being always inversely proportional to the velocity. Again, it appears evident that the chances for C having a great or small initial velocity at B are exactly the same as those for A. Hence, if we compare the velocities of A and C at an instant arbitrarily chosen, the probability of our happening on a time when A is moving slowly may be less than that of our happening on a time when C is moving slowly, and we cannot conclude that the mean kinetic energy of A is greater than that of C; indeed, a comparison of this case with that of the atmosphere, would lead us to expect that the mean kinetic energies of A and C would be equal.

There are cases in which the Boltzmann-Maxwell distribution does not hold. For instance, the case of a large particle confined at the end of a tube, with numerous small particles bombarding it. The mean kinetic energy of the large particle will depend on the range of its motion in the tube. This example would suggest the conclusion that in such cases as gases in contact with solids and liquids, where the molecules of the latter are so confined by molecular forces as to approximate to the condition of the large particle at the end of the tube, the conditions of temperature equilibrium can hardly be determined by the Boltzmann-Maxwell law.

40 Trinity College, Dublin. EDW. P. CULVERWELL.

Poincaré's Thermodynamics.

RENTRANT à Paris après une assez longue absence, je prends seulement connaissance de la dernière lettre de M. Tait. Je ne veux pas continuer une discussion qui ne saurait se prolonger sans dégénérer en une simple logomachie. Il résulte en effet des débats que M. Tait n'attribue pas le même sens que moi à certaines expressions, et en particulier au mot force électromotrice. Il me semble seulement, puisque c'était mon livre qu'il critiquait, que c'était à lui d'adopter mon langage, qui est d'ailleurs celui de tout le monde. Je m'arrêterai donc là, quoiqu'il arrive.

Je suis pourtant obligé d'insister sur un point, parce que je ne veux pas laisser suspecter ma bonne foi. M. Tait a écrit: "Nothing is said, in this connection, about Joule's experiments." En ne tenant pas compte de ces mots "in this connection," j'aurais dénaturé sa pensée. Ces mots ne m'avaient pas échappé. Ils signifient, si je ne me trompe: "dans ses rapports avec la détermination de la température absolue." Et c'est pourquoi, après avoir rappelé que j'avais décrit ces expériences à la page 164, j'ai ajouté que j'avais expliqué à la page 169 comment elles permettent de déterminer la température absolue.

POINCARÉ.

[I need scarcely say that I never dreamt of doubting the good faith of M. Poincaré. What I did (and still do) doubt is my having made my meaning clear to him. For I cannot see how such a discussion could degenerate into a mere war of words. So far as I understand myself, I have been dealing mainly with the validity of certain modes of establishing physical laws, *not* with the mere terms employed in describing the experimental facts on which they are founded.—P. G. T.]

Land and Freshwater Shells Peculiar to the British Isles.

THERE cannot be any reasonable doubt that the inland Mollusca of Britain present some peculiar features, but it is surprising, considering the amount of attention that has been devoted to them, how little exact knowledge we have of this subject. This want of knowledge is doubtless due to two principal causes—first, that so many conchologists consider varieties, and especially slight varieties, to be of little or no importance; and secondly, because those who study our native shells are, as a rule, but ill acquainted with foreign species and varieties. The publication of a list of supposed peculiar forms in the new edition of Dr. Wallace's "Island Life," will, it is hoped, direct attention to this matter. Although this list is more or less provisional, and will doubtless require much alteration as time goes on, I anticipate that the number of forms actually peculiar to our islands, when fully ascertained, will considerably exceed eighty-three, the number at present listed. On the other hand, no doubt, several at present in the list will have to be eventually struck out.

With regard to the peculiar species: *Limnæa involuta* is doubtless an isolated derivative of the *peregra*-type, to which the curious and distinct var. *burnetti* of Scotland may be said to lead. *Assiminea grayana* and *Hydrobia jenkinsi* belong to the brackish-water and salt-marsh fauna, which, as has been well observed, formerly extended far beyond its present limits. To this now-restricted fauna belong many of our peculiar Lepidoptera (see the list in "Island Life," pp. 347-350), and the probability is that most of these are destined shortly to become extinct, as the large copper butterfly (*Chrysophanus dispar*) already is. The fourth species, *Geomalacus maculosus*, is not strictly peculiar, being also found in Portugal; but it is a survival of the Lusitanian fauna, to be classed with numerous plants of similar range, recorded in "Island Life," p. 364. Thus, of the four species given as peculiar, one only is strictly endemic, having regard to its whole history; and the three others are apparently best regarded as survivals of faunæ which were formerly more widely spread.

Turning now to the varieties, we meet with a much larger proportion of truly endemic forms, though from our want of knowledge there is much uncertainty. *Limax marginatus* var. *maculatus* is quite common in parts of Ireland, and as it is a very striking form, it could not easily have been overlooked had it occurred on the Continent. The same applies with perhaps greater force to the beautiful var. *albolateralis* of *Arion ater*, which abounds in parts of Wales. The black variety of *Agriolimax agrestis* is frequent in some places in Yorkshire, and has never been detected on the Continent. But Simroth found it recently on mountains in the Azores, above the zone of cultivation; and in Sicily and Crete there is a melanic form (*panormitanus*), still more differentiated. The var. *griseus* of *A. agrestis*, found in England, and lately by Scharff in Ireland, is grey instead of black, but I am not aware that even this degree of melanism exists on the Continent, though, it is true, they have the dark brown var. *tristis*.

This melanism is well illustrated by other British slugs—namely, two forms of *Limax flavus*, and two of *Amalia sowerbyi*, and may be compared with the well-known cases of melanism so frequent among our Lepidoptera. That there is a strong tendency to the formation of melanic races in these islands cannot, I think, be doubted; and insular melanism elsewhere has been well established as a fact.

There is another class of varieties, noticed especially in the shells, characterized by a slight and yet real difference from the continental type. This sort of variation is as yet very little worked out, but most conchologists who have received common species in numbers from abroad, must have noticed how frequently they have a different *facies* from those familiar to us in Britain, though the actual difference may be so slight that we should hesitate to separate them as varieties. Quite recently, M. Bourguignat has regarded certain British specimens of *Clausilia* and *Unio* as constituting new species. Probably hardly anyone will be found to follow him in this decision, but we know how thoroughly he and his colleagues have ransacked Europe, and especially France, for novelties, so we may rest assured that in all probability these shells represent variations not existing on the Continent.

Another class consists of forms which might be set down by some as mere monstrosities, but which, nevertheless, are local in their distribution. Such are sinistral forms, which occur rarely in many species, but in many instances frequently in certain places. This form of variation is certainly inherited, and in fact has become the character of species and genera. White shells of coloured species are apt to be scoffed at as mere albinos, but the character is undoubtedly an important one, since in *Hyalinia* we have every gradation of species from those which rarely present white varieties, to those which are normally and indeed invariably white. The colourless variety of *Cochlicopa lubrica* is frequent in one or two British localities, at least, but I never heard of its occurrence on the Continent, nor in North America, where the species is abundant.

The sources of possible error, in estimating the number of peculiar forms, are obviously many, and hence the need for prolonged and careful research in the future. *Helix virgata* var. *subdeleta* is very common in England, and I formerly supposed it endemic; but recently Mr. J. T. Carrington found it at Toulon; and *Helix dautezi*, Kobelt, a supposed species from near Algesiras and Gibraltar, is almost precisely identical with it, so far as I can judge from specimens collected by the Rev. J. W. Horsley. The variety *leucozona* of the same species also seemed characteristic of the British fauna, but a form from Toulon differs but slightly from it. *Arion hortensis* var. *fallax*, with orange slime, is given as peculiar. It may, however, be the same as var. *subfuscus*, C. Pfr., which is of a brownish colour, or var. *rufescens*, which is described as reddish or orange. These would look extremely like *fallax* when the latter was covered with slime; but there is an element of uncertainty, since Dr. Scharff has shown that in *A. subfuscus*, Drap., there are two forms, one coloured reddish only by its slime, as in *fallax*, and the other with a yellow pigment in the skin. Similarly, we remain doubtful about *Helix aspersa* var. *lutescens*, a form not rare in some English localities. I know nothing described from the Continent that would agree with it, but when it loses its epidermis it agrees with the description of a French variety, and if we suppose the type of the latter to have been a weathered specimen, the two must be identical.

T. D. A. Cockerell.

Institute of Jamaica, Kingston, Jamaica, May 3.

The Former Connection of Southern Continents.

I read Mr. Lydekker's article on "The Discovery of Australian-like Mammals in South America," in Nature of May 5 (p. 11), with the greatest interest. It is worth while calling attention to a physiographic fact pointing towards a former connection between South America and Southern Africa, such as appears to be required on biological grounds, as pointed out by Mr. Lydekker.

The island of South Georgia in the Antarctic Ocean lat. 54° S., long. 37° W., is composed of clay-slate, the mountains, rising precipitately from the ocean, attaining to altitudes of from 2000 to 3000 metres (Nature, March 27, 1884, p. 509). It is about 1200 miles due east of Cape Horn, and almost exactly one-third of the way between that cape and the Cape of Good Hope.

The full significance of these facts seems hardly to have been realized, especially from a geological point of view. The existence of clay-slate rock forming mountains of an Alpine character indicates with certainty that the island is a portion of a submerged land of great extent. In "The Origin of Mountain Ranges" I have dwelt upon and developed the law that all great mountain ranges (not volcanoes) are thrown up only in areas of great sedimentation. This is true of every mountain range that has been geologically examined, and I do not know of a single exception. Keeping this law well in view, clay-slate mountains of an Alpine character protruding directly from the ocean become invested with deep meaning. They indicate vast horizontal extensions of thick sedimentary deposits which have been subjected to great lateral pressure, and have become ridged up along lines of least resistance. That such sedimentary rocks exist far and wide, forming the ocean bottom about the island of South Georgia, I have not the least doubt. A continental stepping-stone one-third of the way is a somewhat important independent support towards the land connections required by biologists between two great continents.

Park Corner, May 9. T. Mellard Reade.

The Lesser Spotted Woodpecker.

The lesser spotted woodpecker is rather a rare bird, and perhaps the following notes may be worth recording.

This house is in the fields, at the foot of the Cotswolds. Opposite my bedroom window, and only four yards distant, there is a very tall old Lombardy poplar, with a stem two feet thick. One of these birds visited this tree almost every day from the latter part of March till the 12th of this month, coming every morning between 6 and 8, and sometimes also at other hours. He fixed himself always on the same part of the stem, opposite my window, and about 25 feet from the ground; and as there are only a few small branches there, he was very plainly seen He made a remarkable sound, very loud, like the boring of a large auger, continued for one or two seconds, and repeated again and again at short intervals. While the sound continued his whole body seemed in rapid vibration, and he was tapping the tree with extreme rapidity with the point of his beak. During the intervals his head was generally moving quickly from side to side, and his beak was often turned over to plume himself. At this time the crest on his head became often a splendid object. When the sun shone on it, it was like a flash of flame, or the glitter of polished copper foil. The bird was about six inches long, with a rather thick, fluffy-looking body, the tail and back striped black and white, the stripes broadest at the tail. What he was really doing I could not determine. The stem of the tree at that place seems to be hollow, and the bark is cracked, but no hole has been bored, and no insects are seen there. I have had it examined with a long ladder. The bird has now disappeared. I think his nest has been in the stem of an ash-tree in a field not far off. There is a hole in it about the size of a tea-cup, but out of reach. I have not seen his mate, or heard any answering cry.

ALBERT C. MOTT.

The God of the Ethiopians.

IF we were to classify the various African tribes which speak dialects of the Bantu language-branch (the Ethiopians of Herodotus and Pomponius Mela, of Dos Santos and Merolla) according to the names by which they designate the Deity, the greater number of them would be found to fall into two great groups.

Those on the eastern coast worship a god who is known under some form of the word Unkulunkulu.

Tribe.	Name for God.	Root, meaning "great" or "old."	Derivative.
ama Mpondo	Ukulukulu	...	inkulu = great, old ubukulu = greatness ukukulwa = to make great
ama Xosa ama Zulu	Unkulunkulu	Kulu	
be Chuana	(Mokholokholo)[1]	Kholo	ekholo = great
Inhambane tribe	Mulungulu		
Tribe at L. Moero	Mulungu		
,, ,, L. Tanganika	Mulungu		
wa Yao	Mulungu	...	ukulungwa = greatness.
a Nyika	Mulungu	Kulu	
wa Kamba	Mulungu		
ma Konde	Mlungu		
ma Koa, Moçambique	Moloko (Muluku)		
,, Quillimane	Mulugo		
,, Rovumah	Mlugu		
Sofala tribes	Murungu	guru	
,, ,, of Dos Santos	Molungo		
Sena tribes	Murungu	Kuru	ikuru = great
Tete tribes	Muungu	Kuru	
L. Bangweolo tribe	Mungu		
wa Swahili, Zanzibar	Muungu	Ku	Kukuu = old Kwanza = old Kuu = morally Kubwa = physically } great ukuu ukubwa } greatness
,, C. Delgado	Mlungu		
wa Pokomo	Mungo	Ku	
ba Yanzi (Central Africa)	Molongo		
ova Hererò (South-West Africa)	Mukuru	Kuru	ou kuru = antiquity ova kuru = ancestors ova kurupa = old age

[1] This term means simply a very old person, and is not applied to God.

It will be seen that the least corrupted form of the word Unkulunkulu, or Ukulukulu, is found in the Zulu, Xosa, and Pondo dialects of the Kaffir language.

The word itself is formed from the Zulu or Xosa adjective nkulu (root kulu) "great," "grown," hence "adult," "old." Unkulunkulu therefore means primarily "the great (or old) one of the great (or old) one."

The cult paid to Unkulunkulu is a typical instance of that form of monotheism which takes its origin from ancestor worship. The Kaffirs call him their progenitor. Unkulunkulu ukobu wetu.

The above table appears to show that, in Molungo, Mulungulu, Mlugu, or Mungu, the term thus variously modified is derived directly from the full form Unkulunkulu (perhaps originally Munkulunkulu), and thereafter corrupted by phonetic decay, instead of being in each case derived independently, like the archaic form, from the adjective signifying "great" in the language to which it belongs.

The inference, therefore, seems to be that the word Munkulunkulu was used (not necessarily in its present sense) by the common ancestors of all the Eastern Bantu tribes from the River Dana to the Great Fish River, whose descendants still retain the name in their vocabularies, and still hold it in veneration.

On the western coast this name seems replaced by a word which may be most conveniently referred to under its most common form Nzambi.

Tribe.	Name of God.
di Wala i Subu	Nyambi
n Halemoe	Nyama
be Nga ba Seke	Nyambi
o Rungu	Anyambi
m Pongwe	Njambi
m Bete	Ndshambi
a Shira	Aniembie, Njambe
ba Kele	Nshambi
ba Nyombe	Ndzambi
Loango tribes	Zambi
Kabinda tribes	Nzambi Pongo
Ka Kongo tribes Angoy tribes	Zumbi
ba Sundi	Ndzambi à pungo
ba Teke	Ndshambe, Nshami, &c.
ba Yansi	Nzambi, Nyambi
ba Buma	Ndshambi
eshi Kongo	Nzambi, Nzambi ampungo
ba Lunda	Zambi
ba Bunda	Onzambi
ma Ngala	Nsambi
ba Bihe	Nzambi
ba Rotse	Nyampe
ova Herero	Ndyambi

The worship of Nzambi is inextricably commingled with that of fetishes and idols, and has doubtless been still further corrupted by contact with the Portuguese missionaries who were so active in the work of conversion in the Congo Empire in the seventeenth century. But there is reason to believe that in its primitive conception Nzambi was a celestial being or force, a Nature spirit like Zeus or Indra, who ruled the sky or controlled the tempest.

Among the Isubu, *e.g.*, a cognate form signifies "heaven," and such is the case also at Cape Lopez. Winwood Read's Mpongwe raised their hands to heaven when they appealed to Njambi to save them from the hurricane; and his Ashira slave pointed in the same direction when questioned on the subject of the deity. The Manyombe regard Nyambi as heaven, and the Basundi call him the "spirit on high"; and according to Kólbe the otyi Herero term Karunga Ondyambi = "heavenly bestower," "who gives and withholds rain."

The word bears little evidence of change, and is perhaps of comparatively modern origin.

It appears, therefore, that while the Eastern Bantus, who worship Unkulunkulu, indulge in *ahnen-cult*, the western adherents of Nzambi are more or less Nature worshippers. In this respect they appear to approach the Negroes of the Gold, Slave, and Oil Coasts.

A third and smaller, but very distinct group apply the term Morimo or Molimo to their conception of the deity. I refer to the Barolong, the Basuto, the Batlapin, and other clans, which are generally classed together as the Bechuana tribes. "Morimo" is the singular form of a word the plural of which, barimo, balimo, bedimo, bazimo, is found almost universally among the Bantu tribes to denote the spirits of the dead.

The application of the singular form, Morimo, Molimo, in a specialized and restricted sense to the Supreme Being is confined almost entirely to the Bechuana tribes, and has perhaps been only recently used in this monotheistic sense; although John Pory mentions (in his edition of Leo Africanus, A.D. 1600) Muzimo as the one god of the Monomotápa tribes, and Gravenbroek (A.D. 1695) says of the Kaffirs of Zimboe, "Divinitatem aliquem Messimo dictam in lucis summo cultu venerantur."

One other tribe, the Lomwe, who live east of Lake Kilwa among the Namuli Hills, use the word Murimu for God; in this respect differing from their Makoa foes, who worship Mlugu; but this rather leads one to conclude that this tribe is an outlying Bechuana clan. Mr. O'Neill has pointed out the peculiarities of language and architecture which distinguish the Lomwe from their neighbours. W. HAMMOND TOOKE.

Cape Town.

Aurora Borealis.

HAVE any of your readers observed the display of aurora borealis to-night (Wednesday)? I regret that insufficient knowledge of astronomical technicalities does not permit me to describe more exactly the size and position of the display. It appeared between 11 and 11.30 p.m., as white streaks or bands of light, varying in width and intensity, now shooting up a considerable distance, now dying away. It was especially brilliant just to the right of the constellation of Cassiopeia, and this was its furthest eastward limit; it extended more or less across the whole northern sky, and at times was bright enough to dim the stars it covered. The rays appeared to shoot up high into the sky above Cassiopeia. It was a very beautiful phenomenon, and was possibly more distinct in more northern latitudes. WARINGTON STOCK.

S. Paul's Vicarage, Derby, May 18.

THE NEW ELEMENT, MASRIUM.

FURTHER details concerning the new element, whose probable existence was announced in a paper communicated to the Chemical Society at their meeting on April 21, are contributed to the number of the *Chemiker Zeitung* dated May 11. The mineral containing the new substance was discovered in 1890 by Johnson Pacha in the bed of an old river in Upper Egypt long since dried up, but of the former existence of which there are records dating back some 6000 years. Indeed, the name by which it is known in the neighbourhood is "Bahr-bela-Mā," or "river without water." Here and there in the track of the old watercourse are small lakes whose water is of considerable repute for its medicinal value. Specimens of the mineral were sent by Johnson Pacha to the Khedivial Laboratory at Cairo, where it was examined by Messrs. H. Droop Richmond and Hussein Off, the authors of the paper laid before the Chemical Society. The mineral is found to be a fibrous variety of a mixed aluminium and iron alum containing ferrous, manganous, and cobaltous oxides. In addition, however, to these ordinary constituents, a small quantity of the oxide of another element would appear to be present, having properties entirely different from those of any yet known. This element the discoverers have termed *masrium*, from the Arabic name for Egypt, and the mineral has accordingly received the name of *masrite*. The symbol adopted for masrium is Ms.

The composition of masrite may be expressed by the formula $(Al,Fe)_2O_3 . (Ms, Mn, Co, Fe)O . 4SO_3 . 20H_2O$. The amount of masrium present is very small, averaging only about 0·2 per cent., but by working upon fifteen kilograms of the mineral a considerable quantity of the element in the form of various salts has been accumulated. A typical analysis of masrite published in the Proceedings of the Chemical Society is as follows:—

Water	40·35
Insoluble matter	2·61
Alumina	10·62
Ferric oxide	1·63
Masrium oxide	0·20
Manganous oxide	2·56
Cobaltous oxide	1·02
Ferrous oxide	4·23
Sulphuric oxide	36·78
	100·00

Suspicions that the mineral contained some hitherto unknown constituent were first aroused by the fact that when it was dissolved in water, and sulphuretted hydrogen was passed slowly through the solution in presence of acetic acid, instead of the expected black precipitate of sulphide of cobalt a white insoluble substance was first precipitated. This white precipitate continued to form until the new substance in the solution was all used up, when black sulphide of cobalt began to be thrown down. By decantation before the formation of the latter, and subsequent washing with dilute hydrochloric acid, the white substance was isolated in a state of tolerable purity. It was found to dissolve in boiling nitrohydrochloric acid. The solution in *aqua regia* was evaporated in order to remove the excess of acid, and ammonium hydrate added, when a voluminous white precipitate of the hydrate of the new metal was thrown down. The hydrate was washed by decantation, and subsequently dissolved in the minimum excess of sulphuric acid. The solution of the sulphate of the new metal was next evaporated to syrupy consistency, water was added until complete solution was just effected, and the solution mixed with an equal bulk of alcohol. The effect of this addition of alcohol was to cause immediate precipitation of crystals of the sulphate of the new metal, a further crop of which was also obtained upon evaporation. By repeated recrystallization most of the small quantity of iron present was removed. In order to eliminate the last traces of admixed ferrous sulphate, the crystals were redissolved in water, and excess of sodium hydrate added. As the hydrate of the new metal is soluble in excess of soda, the hydrated oxide of iron was readily removed by filtration. Upon the addition of ammonium chloride the white hydrate was precipitated in a gelatinous form; the hydrate was redissolved in hydrochloric acid, and again precipitated and washed. The almost perfectly pure hydrate so obtained was then finally converted to chloride by solution in hydrochloric acid.

In order to obtain data as to the atomic weight of masrium the following determinations were made. A known quantity of the chloride solution was precipitated by ammonia, and the hydrate thus obtained was ignited, and the remaining oxide weighed. A second portion was precipitated by a solution of microcosmic salt in presence of ammonia, and the phosphate obtained ignited and weighed. The chlorine contained in a third portion was determined by means of silver nitrate in the ordinary manner. From the numbers so obtained the equivalent of masrium was calculated. A pure preparation of masrium oxalate was also obtained by precipitating the neutral solution of the chloride with ammonium oxalate, masrium oxalate resembling the oxalate of calcium in being insoluble under such conditions. The precipitated oxalate was washed, dried, and ignited in a combustion tube whose forward end was filled with copper oxide, when the salt was decomposed with elimination of its water of crystallization, which was absorbed and weighed in the usual manner. The residual oxide was also weighed, and the oxalic acid, in another quantity of the salt, was determined by means of a standard solution of potassium permanganate. The crystals of the oxalate were thus found to contain 52·70 per cent. of masrium oxide, 15·85 per cent. of oxalic anhydride, and 31·27 per cent. of water.

From the whole of the analytical data yet obtained, assuming, as the reactions of the salts would indicate, that masrium is a divalent element, the atomic weight would appear to be 228. An element of atomic weight about 225 is, indeed, required to occupy a vacant place in the periodic system in the beryllium-calcium group, and masrium appears likely to be the element in question.

Masrium has only yet been observed to combine with oxygen in one proportion, to form the oxide MsO. Masrium oxide is a white substance much resembling the oxides of the lime group. The chloride, $MsCl_2$, is obtained upon evaporation of a solution of the oxide or hydrate in hydrochloric acid. The nitrate, $Ms(NO_3)_2$, crystallizes from 50 per cent. alcohol, and the crystals contain water, the amount of which has not been determined. The sulphate, $MsSO_4 \cdot 8H_2O$, is a white salt which crystallizes badly from water, but which separates in well-developed crystals from 50 per cent. alcohol. It combines with sulphate of alumina to form an alum, also with potassium sulphate to form a double sulphate. The oxalate above referred to, $MsC_2O_4 \, . \, 8H_2O$, is a white salt, soluble in acetic acid, and also in excess of masrium chloride.

The most important reactions of the salts of masrium, as far as they have yet been studied, are the following. Sulphuretted hydrogen produces no precipitate in presence of hydrochloric acid, but yields a white precipitate in presence of acetic acid. Ammonia precipitates the white hydrate of masrium from solutions of the salts; the hydrate is insoluble in excess of ammonia. Ammonium sulphide and carbonate produce white gelatinous precipitates, likewise insoluble in excess of the reagents. Ammonium phosphate yields a white precipitate of phosphate. Caustic alkalies precipitate the hydrate, but the precipitate is readily soluble in excess of the alkaline hydrate. Potassium ferrocyanide produces a white precipitate which is soluble in excess of masrium chloride, but not in dilute hydrochloric acid. Potassium ferricyanide yields no precipitate. Potassium chromate precipitates yellow chromate of masrium, which is soluble in a further quantity of masrium chloride. Potassium tartrate yields a white tartrate precipitate which dissolves in excess of the reagent, but the solution is not reprecipitated by the addition of ammonia.

Metallic masrium has not yet been obtained. Attempts to isolate it by heating the chloride with sodium under a layer of common salt, and by the electrolysis of a solution of the cyanide proved unsuccessful. The chloride, moreover, is not sufficiently volatile to permit of its vapour density being determined.

From the above interesting reactions, however, it will be evident that masrium possesses a strong individuality, although on the whole behaving somewhat like the metals of the alkaline earths and those of the zinc group. Further work will doubtless afford more definite information concerning its nature and properties. A. E. Tutton.

ON A NEW METHOD OF VIEWING NEWTON'S RINGS.

If we observe the reflection of a rectangular strip of any opaque substance (A) about ¼ inch wide in a piece of plate glass *of about the same thickness*, it appears thus:—

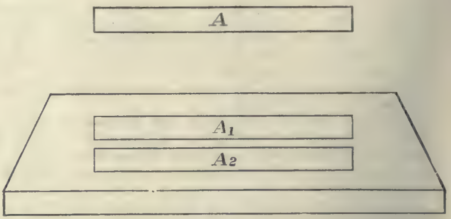

Fig. 1.

A_1 A_2 being the reflections caused by the upper and lower surfaces of the glass respectively.

If a second glass plate, of the same thickness, be added beneath the first, there is a third reflection (A_4) added below A_2 thus, drawing only the reflections for simplicity's sake:—

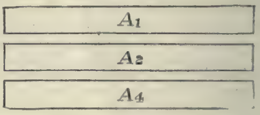

Fig. 2.

Now if the upper slab of glass be *gradually* raised above the lower, the opaque strip remaining in position, the reflection A_2 (Fig. 2), which generally exhibits traces of colour when plate glass is used, splits up into two (A_2 A_3), thus:—

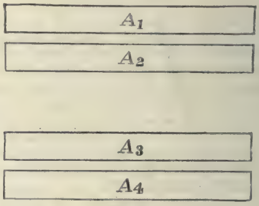

Fig. 3.

Thus it is proved that A_2 (Fig. 2) is the resultant of the reflections of the strip by the lower surface of the upper plate, and the upper surface of the lower plate (A_2 and A_3, Fig. 3, respectively).

In saying that A_1 is the reflection of A caused by the top surface, we mean that light which would fall on that surface and be reflected to the eye is prevented from so doing by the presence of A; and so with respect to the other reflections: thus, if any one of the reflections is not perfectly dark, we can assert that the light seen in it is at any rate not due to reflection (for the first time) at the corresponding surface; *e.g.* A_4 (Fig. 2) appears anything but dark, and we may assert that the light seen in it is not reflected from the bottom surface of the lower plate (at all events for the first time).

Now by means of two similar rectangular strips A and B, placed with their long sides parallel to the surface of the glass, B being further from the observer and from the top plate, it is very easy to arrange them so that B_4—the reflection of B in the lower surface of the lower plate—

apparently coincides with A_1—the reflection of A in the upper surface of the upper plate; and thus, neglecting for the time light which has undergone more than one reflection, we see this A_1B_4 combination of reflections illuminated by light which has undergone reflection at the two inner surfaces only.

It is clear that if we substitute for the two glass plates the apparatus generally sold for exhibiting Newton's rings, we can by this simple method view the rings by the light proceeding from the two inner surfaces only. Thus viewed, the central dark spot appears of a rich velvety black, and the coloured rings very brilliant. The experiment can easily be projected, and the difference in the appearance of the rings on the screen, with and without the opaque screens, is very striking.

The effect of the two screens can be still more simply given by cutting a slit in a piece of blackened cardboard of about the same width as the thickness of one of the glass plates in the rings apparatus; it is almost needless to state that the cardboard in the region of the upper and lower edges of the slit performs the functions of the screens B and A respectively. In this way the backing of the lower glass plate (to get rid of the reflection from its lower surface) may be avoided; an obvious advantage when it is desirable to show the interference in the transmitted as well as in the reflected light.

But the interest of the method does not only lie in its simplicity. Besides affording an easy proof that the rings are caused by light reflected at the inner surfaces of the plates, it also gives a method of seeing and possibly differentiating the interference curves produced by light which has undergone only one reflection, *i.e.* the rings commonly known as Newton's, from the curves produced by the interferences of waves which have undergone two reflections or more (and these last, so far as I know, can only be shown by this method); for if, using the ring apparatus and a single opaque screen, say 3 inches × ⅓ inch, we look into the central reflection (A_2) carefully, two sets of rings, intersecting, can be seen. These cannot be due to light reflected at the points whence the rays which form the primary rings are reflected—by what has gone before.

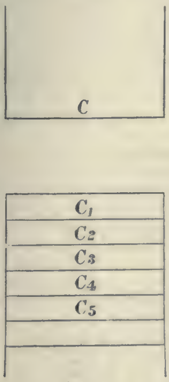

Fig. 4.

To indicate, without attempting for the present any further analysis, how some of the other interference systems may be rendered visible:—Take a strip of blackened cardboard, say 8 inches × 2½ inches, and view its reflections in the Newton's rings apparatus. C (see Fig. 4) being the lower portion of this new screen, its reflection will be seen to consist of a number of shaded strips, C_1, C_2, C_3, &c.; and in each of these will be evident different interference curves (plainer, of course, when monochromatic light is used); in C_1 the primary rings; in C_2 two series of rings crossed; in C_3 still more complicated forms, and so on; each set fainter than the last, the light to which it is due having undergone more reflections than its predecessor. The method suggested for the experimental analysis of these interference systems can only be sketched roughly here. It is, by the use of a second screen, possibly a third, so to combine the reflections of the screens with observations of the consequent alteration in the interference curves, as to completely verify the results a mathematical analysis of the problem would predict. T. C. PORTER.

JEAN SERVAIS STAS.

FEW, if any, among the men of science of the present day have at once done such important work and earned so little popular recognition as Jean Servais Stas. The names of Faraday, Liebig, Dumas, Darwin, have become household words beyond the laboratory and the lecture theatre, and are frequently taken in vain by the purveyors of "science for the million." But, whether among the "classes" or the "masses," if we mention Stas we are apt to be asked, Who was he? What has he done? If we mention his determination of the atomic weights, we have to follow this statement up with a popular lecture on stöchiometry, and are then told that there is not much in it.

Stas was born at Louvain, on August 21, 1813. Like many young men of scientific tastes in the earlier part of the century, he entered upon the study of medicine, and graduated as M.D. But, feeling himself strongly drawn to chemical research, he came to the conclusion that the life of a practising physician was not his true sphere. So early as 1835 he undertook, in conjunction with his friend De Koninck, an investigation of the root-bark of the apple-tree, and discovered phloridzine, an interesting crystalline body. However, at the outset he merely succeeded in obtaining this body in its pure state and in ascertaining its behaviour with reagents. He decided to go further, and to study the constitution and transformations of phloridzine. To this end he stood in need of further instruction. But the methods of organic investigation were at that time little advanced. The art of research was taught only by Liebig at Giessen, and by Dumas at Paris. Stas made choice of Dumas, and after overcoming endless difficulties, was admitted as a pupil in the laboratory of that distinguished Academician.

Here, he resumed the study of phloridzine, and soon succeeded in determining its formula, and those of its principal derivatives. He ascertained that in contact with acids, phloridzine was split into glucose and phloretin, thus belonging to the class of glucosides, bodies the prototype of which had been discovered by Liebig and Wöhler in amygdaline. Berzelius, a man by no means lavish of praise, declared that "from an investigator who has carried out such a research much may be expected."

Impressed with the ability of his pupil, Dumas requested him to undertake a series of investigations in concert with himself. The first of these researches was the examination of the action of potassa-lime on alcohols. They determined that, without exception, alcohols were transformed into corresponding acids. By their powers methylic alcohol yielded formic acid, and ethylic alcohol yielded acetic acid. Fusel-oil gave a valerianic acid exactly agreeing in its properties with the natural valerianic acid—a discovery of great importance considering the paucity of synthetic organic compounds then known. In conjunction with his master, he ascertained the molecular weight of valerianic acid by a determination of its vapour density and by its conversion into tri- and tetra-chlorvalerianic acid, thus justifying their joint belief as to the alcoholic nature of fusel-oil. This conclusion was experimentally confirmed by the conversion of fusel-oil into valeraldehyde.

Immediately after these experiments, Stas, aided by Dumas, entered on the most important work of his life. It had been already found that on the combustion of the more highly carbonized hydrocarbons the sum of the carbon and hydrogen was decidedly greater than the weight of the substance taken for analysis. Two possible explanations were suggested. The excess might be due to a constant error in the method employed, but on careful and frequent repetition of the experiments no such error could be traced; or there remained the possibility that the composition either of carbon dioxide or that of water had not hitherto been accurately determined. In deciding this question Dumas and Stas developed precautions which had never been equalled, and which certainly have not been since surpassed.

It must be remembered that, like Darwin in another department of science, Stas was his own most acute and formidable critic. He seems never to have wearied in devising possible objections to his methods and results, nor of suggesting loop-holes through which errors might possibly have crept. In redetermining the atomic weight of carbon, graphite (natural and artificial) and diamonds were submitted to combustion in a current of perfectly dry oxygen. After the checking and re-checking of results, the operators were forced to conclude that the true atomic weight of carbon was lower than hitherto had been universally accepted. It had been determined by Berzelius and Dulong as 12·24. Dumas and Stas made it simply 12, and confirmed the result by carefully repeated analyses of many substances of known composition. Hence Dumas was led to accept for the atomic weight of oxygen 16, and for that of nitrogen 14. Whilst Dumas and Boussingault executed their determinations in Paris, Stas carried out the same experiments by the same method at Brussels.

These startling results recalled the attention of chemists to the hypothesis of Prout, *i.e.* that the atomic weights of all the elements must be multiples of that of hydrogen ($H = 1$), by a series of whole numbers. Into this question Dumas and Stas threw themselves heart and soul. The experimenters came to separate conclusions. Stas entered the investigation in the full conviction that he should find the principle of Prout exactly confirmed. At the conclusion of his arduous labours, he found his expectations to be "pure illusion."

On the other hand, Dumas sought to retain the hypothesis in a modified form.

Neither of these eminent researchers seems to have paid sufficient attention to the fact that the atomic weights of a considerable number of the elements differ but very slightly, in excess or in deficiency, from the values which the hypothesis of Prout would require. It is quite possible we are here in presence of a residual phenomenon which interferes with the exactitude of the law.

In a paper recently read by Prof. W. Spring before the Belgian Academy of Sciences the speaker gave an abstract of the unpublished researches of Stas. In a certain memoir, "On Silver," was discussed a treatise by Dumas on the quantity of gases absorbed by silver, in which Dumas had conceived doubts as to the conclusions of Stas on the hypothesis of Prout. For the critical purpose Stas prepared absolutely pure silver, containing not a trace of gases nor of kindred metals. At the melting-point of iridium the silver was volatilized without revealing by the spectroscope any trace of sodium, a metal which Dumas had suggested as being possibly present. This pure silver gave the same atomic weight as the silver used previously by Stas. Hence the atomic weight of silver must retain the value which Stas, in his earliest determinations, had assigned to it, and consequently the objections of Dumas fall to the ground.

A second Stas memoir, recently brought to light, fully investigates the question whether the elements sodium, potassium, lithium, calcium, strontium, barium, and thallium can be mutually transformed either by intense heat or by electric action. To carry out his experiments, undertaken in consequence of the views lately expressed, that the spectra of the above metals assume a different aspect at very high temperatures, Stas required materials chemically, or rather spectroscopically, pure. This difficult task took him eleven years to accomplish. As a result he found that even at the melting-point of iridium (from 2200° to 2500°) the spectral lines of the metals remained unaltered, and that consequently the transmutation of elements under the special circumstance is devoid of foundation. The error may have arisen, as Stas suggests, from the use of materials not absolutely pure.

In this course of experiments he verified the distinction pointed out by Bunsen between the flame spectra and the electric spark spectra of metals. The flame spectrum of sodium, even at the most intense temperature, shows the well-known double yellow line. But in the complete electric spark spectrum there appear six double lines, lying respectively in the orange red, the yellow, the greenish-yellow, the green, the greenish blue, and the violet. In the solar spectrum all these six double lines are represented by black lines. In the spectrum of the electric arc may be recognized the six double lines, but in the intense white light of the poles merely the flame spectrum with its double yellow line.

The results of his investigation Stas describes in a discourse entitled "De la Nature de la Lumière Solaire," delivered in 1891. From the coincidence of the lines of the metals as recognized in the spark-spectrum with Frauenhofer's dark lines in the solar spectrum, Stas inferred that the heat and light of the chromosphere were produced by disruptive discharges.

The daily life of Stas was by no means devoid of troubles. Posts of honour, indeed, were showered upon him both in his own country and abroad. He was Vice-President of the Belgian Sanitary Council, technical assessor of the National Bank, a perpetual member of the Council of Administrators of the University of Brussels, a member of the Statistical Bureau, President of the Belgian Academy of Sciences, Honorary Fellow of the Royal Society (which conferred on him the Davy Medal), Corresponding Member of the French Academy of Sciences, and of the majority of the more distinguished Academies and scientific Societies. So far back as 1873, he was elected an honorary member of the German Chemical Society. He was also a Grand Officer of the Belgian Order of Leopold and of the French Legion of Honour, as well as a knight of many orders throughout Europe.

His earliest remunerative position was that of Professor of Chemistry at the Military School of Brussels, a post he successfully filled for more than a quarter of a century. So paltry was the salary attached to this office that he finally petitioned Government for an increase. His request was granted, but in a fashion worse than refusal. He was voted an additional salary of 200 francs—a sum he naturally disdained to accept. Soon after he suffered from an affection of the larynx, which put an end to the delivery of lectures. He was compelled to tender his resignation, but as he had not completed the thirty years of service extorted by law he missed his pension. From this plight he was rescued by the offer of a post in connection with the Mint (Commissaire des Monnaies). The respite from trouble was brief. A syndicate of speculative capitalists proposed to the Government to coin an enormous sum of francs. With the full concurrence of the Minister of Finance, Stas resolutely resisted a scheme he considered dangerous to the interests of the nation. With a change of Ministry the proposed measure was carried. Stas forthwith resigned his post in the Mint, preferring to sacrifice emolument rather than countenance a step which he knew to be detrimental.

Stas not unfrequently engaged in tasks which appeal more directly to the popular mind than the determination of atomic weights. In 1850, Belgium was thrown into excitement by a poisoning case not less sensational than that of Palmer in our own country. It has been said of Belgium that it is less permissible to knock down an *ouvrier* than to murder a nobleman. A Count Bocarme had poisoned his brother-in-law. Had the crime in question been committed by one of the *people*, it might, if not condoned, have been inquired into in a somewhat perfunctory manner. But as the only man to whom suspicion pointed was an aristocrat, a searching investigation was demanded by an indignant public. The chemical investigation conducted by Stas was performed in a masterly manner. The unerring chemist not only detected nicotine poison, but also the exact quantity which had been administered. The guilt of Count Bocarme was much more satisfactorily established than that of Palmer in the Rugeley case.

With characteristic thoroughness Stas was not satisfied with the mere detection and quantitative determination of nicotine. He elaborated a general method for the recognition of organic poisons in chemico-legal investigations. His method of detection, revised and perfected by Julius Otto, is still in general use among toxicologists, under the name of the Stas-Otto process.

At the London International Exhibition of 1862, to Stas was intrusted the report on the industry of oils and fats. The question was discussed whether the old method of saponification by means of alkalies or the recently invented acid saponification was to be preferred. The experiments of Stas demonstrated not only the superiority of the acid process from an economical point of view, but supplied the industrial world with the working details of a method still followed by the manufacturers of stearine candles.

At the initial meeting of the International Committee of Weights and Measures held at Paris in 1875, Stas appeared as the Belgian representative, and took a very active part in its labours. From 1877 to 1879 he was associated partly with H. Ste. Claire Deville, and partly with C. J. Broch in the selection of the metals to be used as standards or prototypes for weights and measures. The alloy selected consisted of 90 per cent. of platinum, and 10 per cent. of iridium. The reports are rich in important observations on the properties of the platinum metals. Unfortunately they have been published, so far as the writer is aware, only in the *Procès-Verbaux du Comité International des Poids et Mesures*, documents not readily accessible. The results have still to find their way into the text-books and metallurgical manuals.

But other labours of the illustrious Belgian chemist have still to be unearthed. At the request of his Government he carried out important researches on metallic alloys for the manufacture of heavy artillery. His copious reports are said to be buried in the archives of the Belgian War Department.

In one quarter only did Stas encounter ill will. He was a champion of the freedom of research and of the independence of the Universities. Hence he came into frequent collision with the "clerical party," which in Belgium plays a *rôle* similar to that of the ethicists and self-constituted "anti-" Societies in Britain.

On January 1, 1891, at the King's New Year reception he courageously reminded the Ministry of the respect which a Government owes to science. We regret we have not met with the text of this discourse, which would be worth reproduction in England. The insulting replies to the bold utterance of Stas were drowned in the loud and general approval of the country.

It is pleasant to add that the personal character of Stas was in harmony with his scientific pre-eminence. He was a man of whom it could be said, "Nihil tetigit quod non ornavit." It was one of his great distinctions that, unlike many illustrious men of science, he was not followed to the grave by the ghosts of dead theories.

NOTES.

Men of science were glad to see that the list of those on whom birthday honours were conferred included Dr. John Evans, who has become a K.C.B.; Mr. W. T. Thiselton Dyer, who has been made a C.I.E.; and Mr. H. H. Howorth, who has been made a K.C.I.E.

The annual visitation of the Royal Observatory at Greenwich will take place on Saturday, June 4.

The Secretary of the British Association Committee for arranging for the occupation of a table at the laboratory of the Marine Biological Association, at Plymouth, requests us to announce that applications for the use of the table during the present summer should be addressed to him (Mr. S. F. Harmer, King's College, Cambridge) not later than Friday, June 10.

Mr. Walter Garstang, M.A., Berkeley Fellow of the Owens College, Manchester, and formerly assistant to the Director of the Marine Biological Association, has been appointed to a naturalist's post upon the staff of the Marine Biological Association at Plymouth, and will have charge of the dredging and collecting operations conducted at the station.

In the fifth Annual Report of the Liverpool Marine Biology Committee (December 1891), Prof. Herdman suggested that the marine biological station might with advantage be changed from Puffin Island to some more easily accessible part of the district, where a fresh area could be investigated. After a careful consideration of several sites, the Committee decided upon Port Erin, at the south end of the Isle of Man, and a suitable building for a marine laboratory, of three rooms, has now been erected, on the beach immediately below the Bellevue Hotel, from plans prepared by Prof. Herdman. This laboratory being ready for workers, and a number of members of the Liverpool Biological and other scientific societies, and also of the Isle of Man Natural History and Antiquarian Society, having expressed an interest in the progress of the undertaking, the Committee have resolved to inaugurate the station by a formal opening on Saturday, June 4. The Lieutenant-Governor of the Island, Mr. Spencer Walpole, has consented to perform the ceremony; and His Excellency, and the Bishop of Sodor and Man, have accepted the invitation of the Committee to be present at a luncheon to be given at the Bellevue Hotel on the occasion.

The Puffin Island Biological Station has been taken over by several members of the staff of the University College of North Wales, Bangor, and will be worked henceforth in connection with that College. Dr. Philip White, the lecturer on zoology, has been appointed director of the station. The island is in full view of, and within easy reach of, the College. The station, as formerly, will be entirely supported by voluntary contributions.

The Marine Biological Laboratory at Wood's Holl, Massachusetts, will be open for investigators from June 1 to August 30. The demand for tables at the laboratory has been so great that the trustees decided some time ago to enlarge the building, and a spacious new wing will be ready for use on July 1. Various courses of instruction in zoology, botany, and microscopical technique will be given, as usual, during the season. Lectures on special subjects will also be delivered by members of the staff.

THE annual *conversazione* of the Society of Arts will take place at the South Kensington Museum on Wednesday evening, June 29.

THE German Anthropological Society will hold its general meeting this year at Ulm, beginning work on July 31. Arrangements have been made for some very pleasant excursions in the neighbourhood.

MAJOR-GENERAL NOBLE, R.A., died on Tuesday, May 17, in his fifty-eighth year. He was well known, not only as the author of books on military subjects, but as the inventor of various scientific instruments connected with the manufacture of guns and gunpowder.

THE University of Heidelberg has conferred the degree of Doctor of Natural Philosophy, *honoris causâ*, on the well-known entomologist, Baron Osten Sacken.

THE beautiful illustrations contained in the *Black and White* Hand-book to the Royal Academy and New Gallery pictures are sure to be welcomed by those who have not already seen them, while to those who have visited these Galleries good reproductions of them will not be amiss. The different coloured tints given to the pictures produce a pleasant variety of impression, while the fidelity to the original details, which is the chief feature of photographic processes, is here thoroughly maintained. Not only the pictures, but the specimens of sculpture, are reproduced in the same way, the results being equally successful. As an introduction to the volume, a brief but interesting account is given of the Royal Academy, together with illustrated biographies of the present Academicians and Associates.

PART I. of Mr. G. J. Romanes's treatise, "Darwin and after Darwin," was published a day or two ago by Messrs. Longmans, Green, and Co. It deals in a critical manner with the distinctively Darwinian theory, or the evidences of evolution as a fact, and of natural selection (with sexual selection) as a method. It is copiously illustrated, for the most part with original woodcuts, and runs to 450 pages. We gather from the preface that Part II. is to treat in a similar spirit of "Post-Darwinian Theories" (heredity, utility, isolation, physiological selection, &c.); and understand that it will probably be ready for publication in the autumn season.

ON April 29, Mauritius was visited by the most terrible hurricane that is known to have ever devastated the island. According to the official telegram from the Acting Governor to the Secretary of State for the Colonies, one-third of Port Louis was destroyed. The Royal College, twenty-four churches and chapels, and many sugar-mills in the country were completely wrecked. There were over 600 deaths in Port Louis; over 300 deaths in the country and over 1000 wounded. "In Port Louis district," the telegram continued, "returns incomplete; probably same amount. No loss among the military. Estimated reduction of crop one-half. Destruction to property enormous. No famine apprehended. All relief measures taken. Relief committee appointed. Panic allayed. Order and quiet reign, but, in presence of thousands of homeless people, pecuniary assistance urgently needed." A public subscription in aid of the sufferers was at once opened by the Lord Mayor. It is to be hoped that the Observatory at Mauritius has been spared. It was thence that Dr. Meldrum announced that at Mauritius the hurricanes and wrecks varied with the sun-spots. We have again a maximum of sun-spots and unprecedented devastation.

THE National Home Reading Society will hold two summer assemblies this year, one at Weston-super-Mare, the other at Bowness. The former will last from June 25 to July 2, the latter from June 27 to July 2. At both meetings science will be well represented among the subjects of study. At Weston-super-Mare, Prof. Lloyd Morgan will lecture on "The Physical History of the Mendip Hills," Sir Robert Ball on "How came the Great Ice Age?", Dr. Dallinger on "Ants: a Study of Sociology and Politics among Insects," Dr. C. W. Kimmins on "Flowers and their Insect Visitors," Mr. A. W. Clayden on "Geological Structure and the Formation of Scenery." At Bowness, Mr. J. E. Marr and Mr. G. Massee will give geological and botanical lectures, but the chief work of the classes in geology and botany will be done in the course of excursions to the places of scientific interest in the Lake District. Both assemblies are likely to be of great service to all who attend them.

MR. GEORGE FORBES arrived on May 6 at the Niagara Falls in company with the executive officers of the Cataract Construction Company. He is acting as the Company's adviser in connection with the plans he submitted to them in 1890 for the transmission of electrical power from the Falls to Buffalo. When the Company appointed a commission of Sir William Thomson, Mascart, Colonel Turrettini, and others to examine the plans, Mr. Forbes gave them as his mature opinion the assurance that they must use alternating currents, and for motors either the ordinary alternator, as first used by Wilde, or the rotating field (Drehstrom), as then used by Tesla, which Mr. Forbes had tested at Pittsburg. These alternating currents to be used with transformers for lighting, and coupled to motors as described for general power, but for electric tramways and some other purposes the alternating motors were to drive continuous current dynamos. These plans were not approved by the commission, and a resolution was nearly passed saying that alternating currents could not be used for the purpose. There was only one dissentient voice, but in the end no resolution was passed. Turrettini and Mascart are now both converted, and Mr. Forbes's plans have been adopted.

MUCH interest has been excited in Philadelphia by a loan collection of objects used in worship, exhibited in the Museum of Archæology of the University of Pennsylvania. Most of the leading religions of the world are represented in the collection. The objects are arranged in accordance with the plan adopted at the Guimet Museum, Paris, and the managers have tried to make up for gaps by notes in the catalogue, which is a closely printed octavo of 174 pages. One result of the exhibition has been that it has brought to light many objects of scientific importance, the significance and value of which were not formerly known by the possessors.

MR. JOHN H. COOKE has made a valuable addition to the Museum of the Malta University. The *Mediterranean Naturalist* describes the gift as a suite of the Maltese fossil Echinoidea, similar to those that have lately been presented by the same gentleman to the British Museum and to the University of Bologna.

A WRITER in the May number of the *Mediterranean Naturalist*, speaking of the colours of the waters of the Mediterranean, says they vary considerably at different seasons of the year and in different localities. During storms and boisterous weather the sea assumes a deep green and sometimes a brownish tint, but when calm and undisturbed it is of a bright, deep blue. In the Bosphorus, and among the islands of the Archipelago, the water is of varying tints, in some places being of a liquid blue graduating into a brighter green, and in others assuming a blue so deep in its intensity as to almost approach a purple.

MR. K. SEKIYA AND MR. F. OMORI contribute to the new volume of the Transactions of the Seismological Society of Japan a most careful paper presenting a comparison of earthquake measurements made in a pit and on the surface ground. It is generally thought that the earthquake motion is considerably less in a pit than on the surface. The conclusion of these inquirers is that for small earthquakes there is no practical difference between the surface and underground observations. For the principal undulations of severe earthquakes a difference may exist, but not to any marked degree; but for small quick vibrations the difference is considerable. Though the calculation for the ripples may be only approximate, their maximum velocities and maximum accelerations are found to be very great, and, in fact, many times greater than those for the principal undulations. Thus, if these ripples are really in great part smoothed away in the pit, it is very likely that in the case of very severe earthquakes there might be less destructive action in deep pits than on the free surface.

THE weather during the past week has been less settled generally than for some time past, although for the most part it was fine and dry over the south and east of England. The distribution of atmospheric pressure was favourable to a westerly type of wind, the barometer being highest over the south of our islands, and lowest over Scotland. An anticyclone was situated over France and Spain throughout the period, and the southern portion of England came greatly under its influence. Several depressions reached the northern parts of the kingdom from the Atlantic, and caused strong winds and gales at some places. The rainfall was considerable in the north and west, amounting to one inch at Stornoway on Monday, but slight in other parts. Bright sunshine was less prevalent; the Meteorological Office report for the week ended the 21st shows that it was below the average in all districts except the Channel Islands. A thick fog occurred over the south of England and parts of the Channel on Sunday. Temperatures have been rather high recently, the maxima reaching 70° and upwards, in places, since Sunday.

THE Weather Bureau of Washington, U.S., has issued, under the title of "Meteorological Work for Agricultural Institutions," a pamphlet containing suggestions as to observations and investigations regarding the relations of climate to agriculture which may with advantage be undertaken at stations situated in agricultural districts, as distinct from the work carried on at observatories and stations established in towns. These suggestions are equally useful for observers in any country; we therefore draw attention to some of the points referred to. (1) Problems of temperature; such as the differences that occur in quiescent air, between places that are close together. These differences depend on solar and terrestrial radiation, the covering of the soil, &c. The subject of protection from frosts also deserves further study. (2) Moisture in the air; especially measurements of evaporation, both from a water surface and from different kinds of soil. The transpiration of plants should also be measured, in such a way that the evaporation from a plant can be compared with the precipitation over the surface occupied by the plant. (3) Condensation and precipitation of moisture. An accurate record of the amount of dew is much wanted; at present, no observations are regularly made. A drosometer has, however, been recently constructed by Kappeller, of Vienna; it is described in the *Meteorologische Zeitschrift* of March last, and is said to give good results. Snow presents many features of interest, such as its density, and the relation of the character of the flake to the character of the weather at the time of the fall. The density of fog, also, should be recorded on some uniform plan, such as the distance at which a slender pole can be seen. The average size and usual forms of hail-stones should also be recorded. (4) Local weather predictions, independent of the daily weather charts, should be carefully studied. The special study of thunderstorms and other local disturbances will result in enabling them to be predicted several hours in advance. Systematic observation with the rain-band spectroscope should also be made. These are but a few of the questions raised in Prof. Harrington's interesting memoir.

WE have received from the Director of the Batavia Observatory (1) rainfall observations in the East Indian Archipelago, and (2) observations made at the Magnetical and Meteorological Observatory, Batavia, both for the year 1890. The daily and monthly rainfall values are given for 193 stations, together with the mean values, calculated from five or more years for 171 stations. The summaries show that the rainfall which accompanied the eastern monsoon was copious over the whole area, and that both in the years 1889 and 1890 the amount during the months of May to September was abnormally high in the eastern parts of the archipelago. In addition to the hourly meteorological observations for 1890, results for twenty-five years, 1866-90, are published in this volume. Dr. Van der Stok considers the fact proved beyond doubt that at Batavia the moon has an appreciable influence on the number of thunderstorms. The cloud curve also shows an increase of cloudiness as the moon rises above the horizon. After the moon has set, the cloudiness does not decrease at a continuous rate, but apparently remains constant.

WE have received the January number of the *Revista do Observatorio*, which is a monthly publication of the Observatory of Rio de Janeiro. This pamphlet, which, by the way, is an index number, contains in tabulated form all the meteorological observations made during that month at the several places from which regular observations can be obtained. The tables show the daily as well as the hourly reduced readings.

THE Technological Museum of Sydney was taken over by the Department of Public Instruction on January 1, 1890. In his first annual report, just received, Mr. J. H. Maiden, the Curator, says the public have shown their appreciation of the usefulness of the Museum by presenting it with a large number of objects, many of which are of great value. The authorities of the Museum have done excellent service by supplying lecturers with specimens, diagrams, and apparatus for illustrative purposes, and by answering questions sent to them by public school teachers—chiefly in country districts—on such matters as the naming of minerals and plants. Technological museums have been, or are being, formed in all those towns in New South Wales which already possess technical colleges. Mr. Maiden says that the matter has been taken up warmly in country districts, and that the formation of local collections is felt to fill up an important gap in the arrangements for technical education in the colony. A flourishing scientific society at West Maitland offered its valuable collection of natural history specimens to the Department of Public Instruction on condition that suitable accommodation should be found for them, and facilities given to the members for access to them. The specimens having been accepted by the Minister on these terms, they form a valuable addition to the West Maitland Technological Museum, constituting a natural history "side" to it. As local scientific societies are always likely to be useful in securing specimens for local museums, and in concentrating the scientific activity of a district to the advantage of the local technical college, and of the district in general, Messrs. Sach and Ross, the resident science masters at Goulburn and Bathurst respectively, have formed scientific societies in their respective cities. These societies have already a good number of members, who meet regularly for the discussion of scientific questions, and they seem to Mr. Maiden to give promise of much usefulness.

At the meeting of the Linnean Society of New South Wales on March 30, Mr. R. Etheridge, Jun., read a paper on, and exhibited, a very peculiar form of "womerah." It is from an unknown locality, but its history is partially known, and a clue is furnished by three very similar weapons in the Macleay Collection from Port Darwin. It is lath-like in form, slightly curved in outline, and altogether a remarkable implement, very unlike anything, to the author's knowledge, previously described.

Dr. G. T. Stevens publishes in *Science* of May 6 an interesting preliminary note on the relations of the motor muscles of the eyes to certain facial expressions. He has for some years closely observed the anomalies of the muscles which govern the movements of the eyes, and has been struck by the fact that remarkable changes often follow the modification of the conditions of these muscles. This led him not only to regard such facial changes with greater care, but to bring to the subject the aid of photography, by means of which alone the expressions could be accurately registered. Photographic portraits giving a direct front view of more than two thousand persons have thus been made. In each case a record, as full as he has been able to obtain, of the state of the eye muscles has been made, and in the majority of cases careful observations have been repeated many times during some weeks or months. Photographs have been taken at various stages of modification of these muscles, so that a comparative study of the face under varying conditions of the eye muscles has been rendered possible. The result of the investigation has been to demonstrate that "certain well-defined types of facial expression are not only associated with, but are dependent upon, certain relative tensions of the oculo-motor muscles." The object of his paper is to present the general characteristics of some of the most typical forms of expression which have their origin in efforts to adjust the eyes.

The first part of a paper on the development of American armour-plate, by Mr. F. Lynwood Garrison, appears in the May number of the Journal of the Franklin Institute. It was the author's original intention to present in the form of a report the results of the recent armour-plate trials at Indian Head. As, however, these trials have been described in an excellent report by the Chief of the Bureau of Ordance of the U.S. Navy, Mr. Garrison has preferred to give a sketch of the development of armour-plate, combining with this the more important details of the official report. He writes from the standpoint of the metallurgist rather than that of the military engineer. At present great interest is centred upon the use of the complex steel alloys and the methods adopted to harden them, and it is to these subjects more particularly that he calls attention. The detailed methods of producing such alloys as well as the several methods for quenching and tempering armour-plate are kept secret by steel manufacturers; but the results are made public at the trials, and "the possible deductions to be made therefrom," says Mr. Garrison, "are patent to every observing and thinking engineer." The fact that he has had exceptionally good opportunities of making such observations is a sufficient reason for the publication of his views.

Some interesting details as to the production of mercury in Russia have been submitted by Prof. Emile Muller, of Taschkent, to the Paris Geographical Society. A bed of this rare metal, discovered at Ekaterinoslav, is now worked with great energy, and 20,000 pouds (320,000 kilogrammes) of pure mercury are obtained. The entire demand for the metal in Russia is supplied from this source, and a surplus of 14,000 pouds (224,000 kilogrammes) is exported. During the past year mercury was discovered in the district of Daghestan, in the Caucasus, and it is expected that the discovery will lead to the growth of a profitable industry in that region.

The vine industry in Bashahr, in the Punjab, was formerly of great importance; but of late years it has declined in consequence of the old trees having been attacked by a disease. Mr. Coldstream, the Deputy Commissioner of Simla, proposes to revive the industry, if possible, and has secured a large number of cuttings for the State.

The *Pioneer Mail* (Allahabad) of May 5 says that locust swarms are reported from the frontier, and that stragglers have been observed again passing over Lahore. It is thought that they have chosen a bad time, as the district is full of the migratory hosts of starlings which come at this season of the year to feed upon wild mulberries, and few of the stragglers are likely to "run the gauntlet" successfully.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mr. M. McPherson; a Crested Porcupine (*Hystrix cristatus*) from Africa, presented by Mr. J. Bullock; a Common Pea-fowl (*Pavo cristatus*) from India, presented by Colonel Bagot Chester; two Yellow-bellied Toads (*Bombinator bombinus*), European, presented by Mr. A. M. Ansler; two Black Bears (*Ursus americanus*) from North America, deposited; a Japanese Deer (*Cervus sika* ♂); a Bennett's Wallaby (*Halmaturus bennetti* ♀); two Himalayan Monauls (*Lophophorus impeyanus*); two Greater Black-backed Gulls (*Larus marinus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Paris Observatory Report.—The annual report on the state of the Paris Observatory for the year 1891, presented by Admiral Mouchez, shows that a considerable amount of work, as in former years, has been accomplished during the past year. After mentioning briefly some of the last reports that have been communicated by those who are undertaking the work of photographically charting the heavens, he gives a *résumé* of the resolutions that have been adopted during the session of 1891. In the table showing the zones allotted to the different Observatories, that given to Greenwich lies between declinations + 90° and + 65°, and that to Oxford between + 31° and + 25°; the number of plates for each zone being 1149 and 1180 respectively. A *résumé* of the meridional observations for the year informs us that no less than 19,458 observations were made, while those of the planets amounted to 570. M. Paul Henry, M. Wolf, and M. Deslandres, have all been busily engaged in their respective sections, their work having been previously mentioned in these columns. The second volume of the catalogue and the second volume of the observed positions (6h. to 12h.) have been completed and published; while Part III. (12h. to 18h.) is still in preparation. The observations for 1884 are now quite finished, and those for 1885 will be ready by the end of this year. The verification of the reduction of the observations made in 1884–86 for the formation of a catalogue of twenty-four stars very near the Pole has already been commenced, and should, when completed, form a most important volume. The individual works that have been published from time to time are also referred to here. The meteorological observations and time service have been continued as usual.

Stars with Remarkable Spectra.—No. 3090 of the *Astronomische Nachrichten* contains a list of stars with remarkable spectra, continued from a former number (3023) of the same periodical, and communicated by T. E. Espin. The number of spectra described here is no less than 121, and the star places have all been brought up to the year 1900.

Comet 1892 Swift (March 6).—The ephemeris of this comet for this week is as follows:—

1892.	R.A. h.	m.	s.	Decl. °	′	log Δ.	log *r*.	Br.
May 27	23	43	17	+35	36·6			
28		45	36	36	2·2			
29		47	54	36	27·4	0·1727	0·1297	0·42
30		50	10	36	52·1			
31		52	24	37	16·2			
1		54	36	37	39·9			
2		56	46	38	3·2	0·1821	0·1429	0·38

The brightness at the time of discovery is taken as unity.

On the 30th the comet will lie in the prolongation of the line joining v and θ Andromedæ, being about twice the distance from θ as is σ.

Light Variations of Y Cygni.—In *Astronomische Nachrichten*, No. 3091, Prof. Dunér discusses the results of his observations, made during the interval April 1891 to April 1892, of Y Cygni, with respect to the cause of the anomalies in the light variations. The number of minima observed amounted to twenty-seven, and on their reduction (together with many others), by grouping the differences between observation and calculation in a particular way, the values for the normal deviations were obtained. These figures showed that the even and odd epochs deviated on the positive and negative sides respectively; and from subsequent calculation, in which $\pm z$ represented constant deviation of the even from the odd minima, the numerical value of z was found not to be constant, but a slowly-increasing quantity. Mr. Yendell, who has previously considered this question, explained the possibility of representing such differences by a periodical function, but Prof. Dunér, assuming a systematic difference between the even and odd epochs, explains them otherwise—"that the star Y Cygni consists of two equally large and bright components, which revolve around their common centre of gravity in an elliptic orbit with a period of revolution of 2d. 23h. 54m. 44s.; the perihelion passages occurring between the even and the odd epochs." If the value of z be found to be real, and not as at present only suspected, we might suppose "a third body, dark or only slightly luminous, which should cause a perturbation in the position of the lines of apsides, such as we recognize in the planets and satellites of our solar system."

To facilitate observation, Prof. Dunér gives an ephemeris for the times of minima expressed in Greenwich mean time. From the latest observations these times may be probably half an hour too late.

Epoch.		Minimum.	d.	h.	m.
1341	1892	June	9	9	33
1361		July	9	8	40
1381		August	8	7	46
1401		September	7	6	52
1421		October	7	5	58
1441		November	6	5	5
1461		December	6	4	12

Nebulæ.—The *Monthly Notices* for April contain some notes on observations of nebulæ made by Mr. Burnham with the 36-inch refractor of the Lick Observatory. The work was undertaken by him during the months of September and October, 1891, in order to give fuller details concerning the descriptions, places, and actual existence of several of these objects included in the general catalogue. All the places derived from the measures are referred to the epoch 1860 of the general catalogue, while the numbers used in all cases are those of Dreyer's general catalogue.

During this survey, several new nebulæ were found, although no attempt was made to search for new objects. The following list includes some of these, together with some of the doubtful nebulæ:—

No. 707.—R.A. 1h. 44m. 31s., Decl. −9° 12′·0. In the immediate vicinity of this a new nebula was found, R.A. 1h. 43m. 31s., Decl. −9° 13′·4.

No. 874.—R.A. 2h. 9m. 43s., Decl. −23° 50′·5. No nebula found near this place. Probably a faint star had been seen, as many are near this position.

No. 942.—R.A. 2h. 21m. 30s., Decl. −11° 27′·2. Near this position are three fainter nebulæ, two of which have been observed before, but one quite new. The places for these three are Neb. (*a*) (new) 2h. 22m. 0 5s., Decl. −11° 27′·9; Neb. (*b*) 2h. 22m. 23·5s., −11° 28′·1; and Neb. (*c*) 2h. 22m. 22·7s., −11° 27′·6.

No. 988.—R.A. 2h. 28m. 34s., Decl. −9° 57′·9. No suggestion of any nebulosity about this star after very careful scrutiny.

Barnard.—R.A. 5h. 14m. 33s., Decl. + 3° 20′·7. In sweeping for this double nebula, another nebula was found in the immediate vicinity, R.A. 5h. 14m. 40s., Decl. + 3° 10′·4.

No. 1988.—R.A. 5h. 29m. 4s., Decl. + 21° 7′·7. Not the least trace of nebulosity here. Dreyer stated that Tempel pointed out that supposed nebula was only a false image of the star. New observation endorses this view.

No. 7447.—R.A. 22h. 53m. 6s., Decl. −11° 16′·7. This object certainly does not exist.

No. 1086.—Near this nebula are two others—

Neb. I. 2h. 40m. 49s., Decl. + 40° 28′·5.
Neb. II. 2h. 41m. 12s., Decl. + 40° 28′·6.

ANNIVERSARY MEETING OF THE ROYAL GEOGRAPHICAL SOCIETY.

The anniversary meeting of the Royal Geographical Society was held on Monday afternoon, when the Right Honourable Sir Mountstuart E. Grant Duff was re-elected President. The following changes have taken place amongst members of the Council:—Sir Henry Rawlinson and Mr. Clements R. Markham have been appointed Vice-Presidents in the room of Sir Frederick Goldsmid and Sir Beauchamp Walker, both of whom remain on the Council, Sir Beauchamp Walker being appointed Foreign Secretary in place of the late Lord Arthur Russell. In addition to the Councillors who have been elected Vice-Presidents, the following have retired by rotation:—Sir George Bowen, Dr. R. N. Cust, Sir Alfred Dent, the Duke of Fife, and General Maclagan. In their place Lieut.-Colonel J. C. Dalton, Sir Arthur Hodgson, Mr. John Murray (the publisher), Mr. E. G. Ravenstein, Sir Rawson Rawson, and Colonel Tanner have been elected.

During the meeting the Royal Medals for the Encouragement of Geographical Science and Discovery were presented, the Founder's Medal being given to Dr. Alfred Russel Wallace in recognition of the high geographical value of his great works, "The Geographical Distribution of Animals," "Island Life," and "The Malay Archipelago," and his further claim for distinction as co-discoverer with Darwin of the theory of natural selection. The Patron's Medal was presented to Mr. Edward Whymper for the results of his journey in 1879–80, recorded in his work, "Travels among the Great Andes of the Equator," London, 1892, 2 vols., besides a volume on the aneroid barometer. The Murchison Grant for 1892 went to Mr. Robert Swan, surveyor and geologist, who accompanied Mr. Bent in his expedition to Mashonaland, making a careful route-map of the country traversed down to the East Coast at Beira; the Back Grant to the Rev. James Sibree, for his many years' work on the geography and bibliography of Madagascar; the Cuthbert Peek Grant to Mr. Charles W. Campbell, for his important journeys in Korea; and the Gill Memorial to Mr. G. H. Garrett, for important geographical work done during the past fifteen years in Sierra Leone. Mr. Mackinder and Mr. Buchanan gave a short account of the Geographical Lectureships at Oxford and Cambridge. The scholarships and prizes given by the Royal Geographical Society to students in training colleges for 1892 were also presented.

The President delivered the annual address on the progress of geography, in the course of which, after referring to the evening meetings and to the Proceedings for the past year, he said:—

'With our meetings all Fellows of the Society who live in London, and with our Proceedings all Fellows of the Society, may be taken to be more or less familiar, but our Fellows by their contributions do a great deal more for their science than to make it possible to hold meetings and to publish Proceedings; nor does it seem unadvisable to remind them, from time to time, what they are doing in other ways for science and the body politic. They are aware that an annual vote of £500 is taken in the Estimates in aid of the Society's finances. In return for that it is bound to keep open for the public at large, and does keep open, a map collection of great importance. During the last year some 2500 persons visited the map room, which is in charge, as you all know, of Mr. Coles, a most competent officer; but if we had more room we could be much more useful. We could, for example, store, in such a way as to make it quite easy to refer to them, all the 25-inch Ordnance Survey maps. That at present is perfectly out of the question. We should like also, if we had the space, to have a room where any Member of Parliament or person holding an official position could at once be supplied with all the information he could desire upon any of the innumerable questions where politics and administration cross the frontiers of geography.

"Another of our duties is to collect and keep together a large collection of books, maps, diagrams, photographs, and other helps to earth-knowledge. Of the first of these we have about 40,000, valued at not less than £10,000. Of the second and third, about 50,000 maps and charts and 7000 atlases; and of the fourth about 4000 copies, together valued at about £8000. We keep, too, a stock of instruments, which we lend from time to time to travellers who satisfy us that they can use them; £680 worth of these have been lent to Government officials since 1888. A further department of our activity is map-making. We have recently produced a large-scale map of East Central Africa, as well as maps of Persia and Tibet, edited respectively by Mr. George Curzon and General J. T. Walker, while we are constantly publishing in our Proceedings original maps which, but for us, would never see the light at all, or, if they did, only after an amount of delay which would greatly impair their usefulness.

"The same officer who presides so well over our map collection renders very useful services to the public, by giving instruction in surveying and practical astronomy to persons who are going into countries the geography of which is little known. Forty-eight servants of the Government, soldiers, sailors, and others, of whom twenty-one were employed on special service and boundary commissions, have recently taken advantage of this teaching. We receive too as students, at the desire of the Colonial Office, all officials who come to us before going out to West Africa, and pay half their fees, while our advice and help is always at the disposal of any of the Government Offices which desire to consult us on the choice and purchase of instruments.

"Another very important function which our Fellows enable the Council to fulfil, is the granting of direct subventions to intending explorers, and you all know what large sums have been given at various times for such purposes. Mr. Conway, a most experienced mountaineer, and a man of large scientific knowledge, started in the beginning of this year to explore the glaciers of the Karakorum. He received from us £250 towards his expenses, and a conditional promise of more.

"To Mr. Pratt, who read at one of the Society's meetings a very valuable paper on North-Western China more than a year ago, and who is now going through the regions, first clearly revealed to science by Mr. Bates in his delightful "Naturalist on the Amazons," to explore the still unknown or little known regions in the extensive valley of that great river, we have given a grant of £100, and have lent him instruments. If he adds considerably to geographical knowledge, our contribution may be increased at a later period. We have given a small grant in aid of a proposed inquiry into the Houssa language and people. To Dr. Nansen we have voted £300. The object of his expedition, it should be remembered, is not so much to reach the North Pole, as to explore the unknown Arctic region. This he proposes to effect, not by following the coast line of Greenland or Franz Josef Land, which might be the best plan *if* their coast lines extend much beyond the points already known; but to reach the edge of the hitherto untravelled region by the help of the surface currents which he believes cross the Polar region from Siberia towards Greenland.

"In the beginning of the year we published a circular prepared by the Orthographical Committee of the Council upon the spelling of geographical names. This was done in pursuance of the policy announced in the Proceedings for 1885, p. 535—a policy in which we were encouraged by observing that the charts and maps issued during the last six years by the Admiralty and War Office have conformed to our views; that the Foreign and Colonial Offices have done the same, and that the Government of the United States of America has adopted a very similar system.

"The death of Mr. Bates rendered vacant the office of Assistant Secretary, and the Council felt sure that it would consult the best interests of the Society by promoting to that position our late librarian, Mr. Keltie, who was made at the same time editor of the Society's publications. The vacancy caused by this promotion was filled after a very careful consideration by the appointment of Dr. H. R. Mill, who has done much already for scientific geography. Our cartographical department has been strengthened by the accession of Mr. Darbishire, a highly promising pupil of Mr. Mackinder's at Oxford, who has also had an excellent German training.

"The Council has requested three gentlemen, well known to the Society, to represent it at one or other of the Congresses to be held at Madrid, in the neighbourhood of Huelva, and at Genoa, in honour of the fourth centenary of the discovery of America by Columbus. The attention of many I address was doubtless called to the Congress at Berne, where, by the way, England 'was conspicuous by its absence' in the Educational Section. A strong wish was expressed there that the next Congress should meet in London, and the necessary steps have been taken to comply with that wish. A committee, of which Major Darwin is the head, is now engaged in initiating arrangements for a Geographical Congress to be held in 1895.

"Hardly inferior in importance to the duty of assisting well-considered exploration and supplying true explorers with an audience to applaud their discoveries—a duty laid upon the Society by all its past—is the duty laid upon it by the necessities of the present to assist in the wider diffusion of geographical instruction.

"In our attempts to increase the amount and improve the quality of geographical teaching in the country we had to put up with some grievous disappointments. We began as far back as 1869 by giving medals to be competed for by the principal English schools. Two schools, and two only, distinguished themselves in the competitions—Dulwich College and Liverpool College. As to the fourteen others, the less said the better. The Society, however, had no idea of allowing itself to be beaten by the *vis inertiæ* or *laches* of individuals. Mr. Freshfield, one of our honorary secretaries, himself an Etonian, was possessed with a perfect passion for giving to others the advantages in respect of geographical instruction which he had not enjoyed in boyhood. Mr. Bates, our late excellent assistant secretary, pondered long, as was his wont, as to whether we ought to throw a substantial portion of our strength into improving education, and having come to an affirmative conclusion, took the matter up with characteristic energy. The Council was of the same mind, and ere long it was determined—

"1. To send Mr. Keltie to report upon geographical teaching at home and abroad.

"2. To open, under the auspices of the Society, an Educational Exhibition, in which all the best appliances for the teaching of geography should be brought together.

"Mr. Keltie accordingly commenced his investigations, travelling very widely while he carried them into effect. His Report was published, and excited much attention. The Exhibition was open during December 1885 and January 1886, and was visited by several thousands of persons interested in education. The collection contained in it has been lent to the Teachers' Guild, and is now exhibited in the museum of that body in Gower Street.

"The movement thus inaugurated resulted in various changes in our policy. We concluded a treaty with the University of Oxford in 1887, and with Cambridge in 1888, by which it was stipulated that we should go shares with each of these learned bodies in paying the salary of a lecturer to teach geography to such of their members as choose to avail themselves of his services. An argument, if it deserves the name, has sometimes been advanced, to the effect that we should not teach geography at our Universities, 'because it is a graphy and not a logy!'

"Throughout Germany the question has been settled. In that country, as well as in Austria and elsewhere, professors of geography are lecturing, and lecturing to excellent purpose, without interfering either with the domain of their historical colleagues on the one side or their geological colleagues on the other. Whether it is taught or not taught in schools and Universities, geography must in the nature of things rule the territory in which the sciences relating to organic life, from history down to the structure of the humblest animate thing, meet the sciences which have to do with inorganic nature.

Call it a 'graphy,' or a 'logy,' or a 'Kunde,' or what you please, it remains the body of knowledge which has to do with the theatre of the activity of man and all things that have life. We may stunt and injure the activity of the next generation by refusing to teach it, but eventually it must obtain the position which the greatest of living systematic botanists claimed for it in 1886. 'It must permeate,' he said, 'the whole of education to the termination of the University career, every subject taught having a geographical aspect.'

"When, in spite of foolish objections, we had sown the seeds of what we may hope, having regard to the slowness with which trees grow in our English climate, to be vigorous saplings about the end of the century and respectable denizens of the forest in the year 2000, we turned to the training schools, and concluded a convention with the Education Department, whereby we engaged to give certain scholarships and prizes to such of their students as were reported by the Inspectors of Schools charged with the conduct of the examinations to be worthy of those distinctions. Then, further, we entered into arrangements in 1888, with the directing Delegates of the Oxford University Extension Lectures, by which we agreed to give, on certain conditions, a yearly grant of £60, in aid of geographical teaching. We have resolved to set on foot regular courses of geographical lectures in London, which will commence probably next November, and be given by Mr. Mackinder and other competent geographers.

"Our very latest measures for the improvement of geographical education have been :—

"1. To agree to some modifications in the distribution of the prizes to the training colleges which the officers of the Education Department advised, and which will better promote the object which the Society has in view.

"2. To co-operate with the Manchester Geographical Society in assisting the governing body of the Victoria University to introduce geographical teaching into the curriculum by making a substantial grant for that purpose.

"3. To award a travelling scholarship of £100—our share being £50—after an examination held at Oxford. This was gained by a young man, Mr. Grundy, who was bound, under the conditions prescribed, to travel for at least three months in one of a number of districts from which he might take his choice, and communicate the results to us. He has selected Bœotia, and will, I make no doubt, furnish the Society ere long with some valuable information.

"We continue the prizes given at the Oxford and Cambridge local examinations, and to the boys of the training ships. These belong to the same period of our history as the Public School medals, but with them we have been more successful. We are in correspondence with the Scotch Education Department as to the best method of further encouraging geographical study on the other side of the Tweed, where it has long been comparatively popular.

"It seems to me quite certain that this part of our activity will fill a larger and larger space in the thoughts of all of us for a long time to come. The day will arrive when it will be of very little importance. Common-sense has a way of conquering in the end, and the proposition that it is highly desirable for intelligent creatures inhabiting this planet to have a good general notion of the opportunities which it affords them is so self-evident, that one would think it did not require a very numerous and powerful Society to urge its general acceptance upon the scholastic world.

"Geography and history are relegated to a subordinate place in almost all our schools which consider themselves to belong to the first or second rank, while the utmost prominence is given, not to reading the classics, to getting thoroughly imbued with classical ideas, and to having the mind filled with whatever of good and great the ancient world has bequeathed to us, but largely to accomplishments in the way of turning out pretty pieces of verse or prose, in the ancient tongues, which bear much the same relations to serious intellectual pursuits as do to the proper works and ways of an intelligent dog the art of jumping through a hoop filled with paper, or that of balancing on his nose a piece of biscuit till he is told that it is 'paid for.' Educators who have given the best years of their lives to these accomplishments naturally abhor the idea of diminishing their importance, and when they are asked to find a reasonable place for history and geography in their schools they piteously point to their time-tables and say, 'How are we to manage it?' Manage it by the elimination of rubbish. Put composition in the ancient tongues as a piece of regular 'school business' behind the fire, and greatly diminish the amount of time given to learning by heart in the interest of Latin and Greek composition. Neither geography nor history will ever obtain their proper position in education until we can get rid of the superstition as distinguished from the religion of the classics. No reasonable man who has a competent acquaintance with the subject can tolerate the idea of the classics being neglected. They form a most important part, and must always continue to form a most important part of literature, and literature is for a large class of minds a most excellent training. For a great many minds, however, it is not an excellent training, and to a considerable proportion of those susceptible of being trained by it the ancient languages present no attractions. I maintain that for a great many minds geography and history, well and carefully taught, would be much more educative than the two studies which as late as the time at which I took my degree, not quite forty-two years ago, almost absolutely monopolized attention in Oxford and Cambridge. Then, too, we must remember that while for everybody classics are mainly educative, and in a much less degree instructive, and while mathematics are instructive in a high degree only to those who are going into any of the no doubt numerous careers for which they are essential, geography and history are instructive in a very high degree to all, even to those to whom they are not educative.

"What I think we as a Society should keep chiefly in view is to try to have a clear and connected account of the leading facts which are known about the theatre of man's activity, together with an intelligent idea of the leading causes which have brought those facts about very much more widely extended through all ranks than they are now. We must keep our aims moderate in geography. There are undeniably a few persons to whom both geography and history, teach them as you will, are thoroughly abhorrent. Well, teach the very minimum of them to such people. A large number of people can be cultivated, and very highly cultivated, better through geography and history than anything else. All I ask for is, that in the education of such people these two sciences should play a very much larger part than they do now. I think that if we could see some thoroughly good hand-book of physical geography and another of political and commercial geography made part of the teaching of all secondary schools, and a subject of the leaving examination which should be borrowed from Germany, if we continue to hold up as we are doing at Oxford, and elsewhere, a very high standard of professorial teaching in our subject, while we at the same time persist in the other lines of educational activity to which I have alluded, we should have done a good deal ; but it is far from improbable that we may ere long see our way to giving further stimulus to sound geographical teaching in various parts of the country. The Society, however, may be assured that we will remember the maxim *Festina lente*, and not waste the resources with which its members supply us in any rash experiments. Geography is rooted in the physical sciences, and makes each of them tributary to her, while history which is not rooted in geography, and which does not learn from geography all it has to teach about the existing conditions of man's dwelling-place, is simply bad history."

The President then referred to the year's exploration. Herr Merzbacher's work in the Caucasus, and Mr. Howell's ascent of Oræfa Jökull in Iceland, were noticed as the chief mountaineering feats. In Asia military exploration had gone on steadily on the northern frontiers, and the Society was making efforts to have the results of such work made more accessible to the public. Lord Lamington's journey in the Shan States, Captain Bower's and Dr. Thorold's adventurous crossing of Tibet also opened up new ground. In Africa Mr. E. A. Floyer crossed the Egyptian Desert from Assouan to the Red Sea ; and in the region of the Great Lakes Captain Lugard, Emin Pasha, Dr. Stuhlman, and the late Father Schynse have added to our knowledge. The Italians have been energetic in exploring Somali-land, and the French, despite the disaster to M. Crampel, have not abandoned their efforts to reach Lake Chad from the west. Captain Gallwey and Mr. Gilbert T. Carter have made important discoveries in Lagos and Benin. Mr. Bent's well-known exploration of Zimbabwe, and Mr. Joseph Thomson's study of Lake Bangweola, which ill-health still prevents him from recording, are the most important pieces of work in South Africa.

The semi-Arctic regions of Labrador and Alaska have received much attention in America, and their topography is being more definitely ascertained.

In Australia the Elder expedition has unfortunately collapsed, after doing much good work, but Sir William MacGregor has been very active in opening up British New Guinea.

Reference was also made to the progress of the hydrographic surveys in different parts of the world.

In the evening the anniversary dinner of the Society took place at the Whitehall Rooms, Hôtel Métropole, and was attended by a large gathering of Fellows, with many of the leading scientific men and members of the Diplomatic Service as guests. The President occupied the chair. A clever speech was delivered by Mr. Whymper, in response to the toast of "The Medallists." Mr. Bryce, Colonel Maurice, Prof. Flower, Mr. W. T. Thiselton Dyer, and Mr. Norman Lockyer responded to the toast of "The Allied Sciences and Sister Departments."

TRANSFORMERS.[1]

ALTHOUGH transformers are in constant use for changing alternating currents of electricity from high to low or from low to high potential, exact calculations concerning them have hitherto been looked upon by scientific men as impossible because of the complicated law of magnetization which must subsist in iron. Calculations on the assumption of constant magnetic permeability were thought to be worthless, therefore, although these were the only ones which could be made. Certain graphical methods of representing what occurred were, however, based upon the constant permeability hypothesis, and although such graphical methods could only be useful in illustrative work, they were thought to be accurate enough when great accuracy was impossible. The absence of a theory was supplied by vague statements regarding the effects of hysteresis; and the cycle of magnetization being supposed to be exactly the same, however rapidly performed, and Foucault currents being ignored, it was possible for any writer to get his literature on this subject published and read and commented upon.

Prof. Perry has for a long time preached the doctrine that the only theory of the transformer that can be carefully worked out—namely, that in which hysteresis is ignored—ought to be worked out and compared with experimental results; and he insisted that when the known phenomena of magnetic leakage and slight saturation and Foucault currents are taken into account, the results of this theory explain all observed experimental results.

In the present paper he takes up the general case of a transformer with many primary and secondary circuits with magnetic leakage, Foucault currents, choking coils and condensers in series with or in parallel to any or all the circuits. He clears away much of the old difficulty by proving that, in all calculations except that of the idle current supplied to an unloaded transformer, in all practical cases, exactly the same answers are obtained, to four significant figures or more, whether we assume the most complicated of hysteresis cycles or whether we assume the very simplest, which is that of constant permeability. It is, for example, interesting to observe that a formula never hitherto published as correct, often enough used by manufacturers as sufficiently correct for practical purposes, is really a very correct formula. It is also shown that the mathematical difficulties introduced by condensers and magnetic leakage efface themselves completely now that the complete problem has been attacked, and that the numerical working out of the most complicated cases is a very simple matter.

The one problem on transformers in which it is necessary to consider the law of magnetization of the iron—namely, the calculation of the idle current when the transformer is unloaded—is solved by the author in general terms, and he gives a simpler solution, which in his opinion agrees with all experimental results, although it assumes that there is no hysteresis in the iron.

SCIENTIFIC SERIALS.

THE only important paper in the *Nuovo Giornale Botanico Italiano* for April is an elaborate one by Signor G. Paoletti on the movements of the leaves of *Porlieria hygrometrica*. The structure of the plant is described in detail, and especially the anatomy of the "motor nodes" of the leaves and of the leaflets. He distinguishes in them two kinds of tissue, a motor system and a passive system. The cause of the movements appears to reside in the protoplasm and in the osmotic properties of the cell-sap. The author is unable to find in the leaves any hygrometric properties, the supposed presence of which was the reason for the specific name of the plant. The paper is illustrated by four plates.

THE greater number of the papers in the 2nd, 3rd, and 4th numbers of the *Bullettino della Società Botanica Italiana* for 1892 are chiefly of local interest to Italian botanists. Among those of a wider scope are the following:—Signor L. Macchiati describes an appearance presented by *Navicula elliptica*, which he considers strongly to confirm Castracane's view of the occasional reproduction of diatoms by internal germs.—Signor P. Pichi gives the results of experiments on the power of the vine to absorp sulphate of copper through the roots as a specific against the attacks of *Peronospora*. Analysis of the ash showed the presence of copper in leaves taken from both the upper and the lower branches.—Signor L. Piccioli gives some details respecting the destruction of plants by different kinds of land and freshwater snails, with the amount which is devoured of different plants. This is generally greater in the spring than in the summer.

IN the *Botanical Gazette* for April, Mr. G. E. Stone describes and figures a self-registering auxanometer, which can be readily constructed, of much simpler construction than those at present in use in botanical laboratories.—Mr. Conway Macmillan offers suggestions as to the classification of the Metaphyta, *i.e.* of the higher forms of vegetable life.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 28.—"On some Phenomena connected with Cloudy Condensation." By John Aitken, F.R.S., F.R.S.E.

This paper is divided into two parts. In Part I. are described the different influences which cause the condensation of a jet of steam when mixing with ordinary air to become more dense than it generally is, and in Part II. certain colour phenomena are described which have been observed when cloudy condensation is made to take place under certain conditions.

PART I.

Steam Jets.

It had been previously shown that when a jet of steam is electrified the condensation suddenly becomes very dense. In addition to electrification, it is found that this change in the appearance of the jet may be produced by other four causes. There are thus five influences capable of producing the dense form of condensation. These are: 1st, electricity; 2nd, a large number of dust particles in the air; 3rd, cold or low temperature of the air; 4th, high pressure of the steam; and, 5th, obstructions in front of the nozzle, and rough or irregular nozzles.

1st. *Electrification.*

It is shown that the mere presence of an electrified body has no influence on the steam jet. In order to produce the increased density the water particles in the jet must be electrified, either by direct discharge, or by an inductive discharge, effected by means either of a point or a flame.

The increased density produced by electrification is due to an increase in the number of water particles in the jet, by the electrification preventing the small drops coming into contact by their mutual repulsions, in the same manner as the water drops in Lord Rayleigh's experiments with water jets, which scatter more when electrified than when not electrified. The coalescence of the drops in water jets takes place only under the disturbance produced by the presence of an electrified body, while such a disturbance produces no effect on steam jets.

Other experiments point to the conclusion that the increase in the density is due to an increase in the number, and not to an increase in the size, of the drops. For instance, if steam is blown into a receiver full of air in which there are many nuclei, the condensation is dense, and, if there are few nuclei, the clouding is thin. The same holds good for the clouding produced by expanding moist air. If many dust particles be present, the clouding is dense; if few, it is thin. The action of the electricity does not seem to be positive, as it has no effect on a mixture of hot moist air and cold air. It seems rather to prevent something which takes place in the jet under ordinary conditions. The particles in a jet being in rapid movement, there are frequent collisions, and consequent coalescence of the drops, but when the particles are electrified they repel each other, and coalescence is prevented.

---

[1] Abstract of a paper read at the Royal Society, May 12, by Prof. Perry, D.Sc., F.R.S.

The jet on becoming dense emits a peculiar sound, which is the same whatever be the cause of the increased density. But, when electrified, along with this sound there is another, due to the discharge of the electricity, which causes the electrified jet to appear to make a louder noise. The jet, instead of changing suddenly in appearance when electrified, may be made to change very gradually, either by electrifying it by means of a very sharp point, or by aiding the discharge by a flame. Under these conditions, the jet emits only the sound produced when dense from any of the other causes.

2nd. *A Large Number of Dust Particles in the Air.*

Flame has not been found to have any influence on the steam jet, but on bringing the products of combustion to the jet, it at once becomes dense, and remains dense so long as the supply is kept up, and the jet has exactly the same appearance as if electrified. When in this condition electricity does not increase its density any further. The increased density is here due to the large number of dust nuclei, causing a great increase in the number of water drops, and these being very small, they will have less independent movement, and therefore fewer collisions, and the reduction in number from this cause will therefore be very slight.

3rd. *Low Temperature of the Air.*

When a steam jet condenses in air at ordinary temperatures it has but little density, but, if the open end of a metal tube cooled to 45° be held near the origin of the jet, the condensation at once becomes dense, and neither electrification nor an increased supply of nuclei makes it any denser. In a room at a temperature of 46° the jet is always dense, and neither electricity nor the products of combustion have any effect on it, but when the temperature rises to 47° the jet begins to get a little less dense, and electricity now increases its density slightly. At 50° the jet is much thinner, and both electricity and the products of combustion have a marked effect on it. The change produced by the cold air cannot be entirely due to the lower temperature causing more vapour to be condensed, as the fall of temperature is slight, while the increase in density is great. The increased density is shown to be due to a change which takes place in the films of the small drops with the fall of temperature. When the temperature is above a certain point, the films have no repulsive action, and the drops coalesce on collision; whereas when cooled below a certain temperature the well-known repulsion comes into play and prevents coalescence. This was proved by repeating Lord Rayleigh's experiments with water jets. When the temperature of the water was over 160°, the drops had no tendency to scatter, and the presence of an electrified body had no influence on the jet. It was only when the temperature fell that the scattering began, and the electrical disturbance produced coalescence. The effect of the low temperature is the same as that of electrification: both of them prevent the water drops coming into contact, one by electrical repulsion, and the other by the repulsive action of the water films, and the result is the same—namely, an increase, or rather a prevention of the decrease, in the number of the particles, and a consequent increase in the density of the clouding.

4th. *High Pressure of the Steam.*

Below a temperature of 46° the jet is dense at all pressures, and as the temperature rises the density decreases, but the density may be made to return by increasing the pressure. The increased density of the high-pressure steam jet is due to an increase in the number of drops produced, (1) by the jet being more cooled by the greater amount of air taken into it; (2) by a larger supply of dust nuclei; and (3) owing to the rate at which the condensation is made to take place, a larger number of dust particles are forced to become centres of condensation.

5th. *Rough Nozzles and Obstruction in Front of the Nozzle.*

Rough nozzles and obstruction in front of the nozzle are found to act in the same way as increase of pressure: they aid pressure in producing its effects with a less velocity of steam. They act by producing eddies, which mix more air with the steam, so lowering the temperature of the jet, increasing the number of dust nuclei, and quickening the rate of condensation.

The seat of sensitiveness to all these influences causing the condensation in the jet to become dense is near the nozzle. Both low temperature and obstructions have an effect only when they act very close to the nozzle; while electricity and increase in number of nuclei have a slight, but rapidly diminishing, influence to a distance of 3 or 4 cm. from the nozzle.

PART II.

Colour Phenomena connected with Cloudy Condensation.

The manner in which cloudy condensation changes after it is formed is pointed out, and it is also shown that the number of dust particles which become centres of condensation depends on the rate at which the condensation is made to take place, slow condensation producing few water particles and thin clouding, while quick condensation produces a large number of water particles and dense clouding. It is only when the dust particles are few that all of them become active centres of condensation.

Colour Phenomena in Steam Jets.

Colour has been seen by Principal Forbes and others in the steam escaping from engine boilers, but these colour phenomena have as yet been but little studied. For observing the colour in steam jets, the author has found it to be a great advantage to inclose the jet in a tube, and examine the effect through some length of condensing steam. Steam by itself has no colour in moderate lengths, but when mixed with a certain amount of cold air, and a certain quantity of dust, very beautiful colours are produced. A jet of steam is allowed to blow into the open end of a tube, and the amount of dusty air entering with it is regulated to the necessary amount. When the jet is condensing under ordinary conditions, the colour of the transmitted light varies from greens to blues of various depths, according to the conditions. The colour may be made very pale or extremely deep by varying the conditions. If the condensation in the jet be made to change and become dense by any of the influences already mentioned, the colour changes, and generally becomes of a yellowish-brown.

This yellow colour, seen through steam when the jet is electrified, has been previously observed. It was thought that the colour was due to the electricity, and that the experiment explained the lurid colour of thunder-clouds. There does not, however, seem to be any connection between the electrification and the colour, as the transmitted light becomes of the same lurid hue when the jet is made dense by any of the other influences.

The yellow colours seen through steam are not generally so fine as the greens and blues, but when the density is due to high-pressure steam the yellow is very fine.

Colours in Cloudy Condensation produced by Expansion.

No colours had been previously seen in the light transmitted directly through the clouded air produced by expanding saturated air in a receiver. It was thought this was due to the slowness with which this process is generally made to take place in the expansion experiments. On arranging an experiment to make the rate of condensation quick, beautiful colours were seen on looking through the clouded air. An air pump was connected with a metal tube provided with glass ends. The capacity of the tube was small compared with the capacity of the receivers usually used in these experiments. When the air in the tube was suddenly expanded, the light passing through it became beautifully coloured, and the colour, and the depth of the colour, varied with the conditions. With few dust particles in the air, a slight expansion made the transmitted light blue; a greater expansion changed it to green, and then to yellow; and when the expansion was still further increased the colour changed, and a second blue made its appearance, followed by a second green and yellow. But, if very many particles were present, the same amount of expansion which produced the second yellow only gave a very deep blue. When it is desired to produce these colour phenomena on a large scale a vacuum receiver is used. This receiver is connected with the experimental tube or flask by means of a pipe fitted with a stop-cock. After a partial vacuum has been made in the receiver, the connection between it and the flask or tube in which the colours are to be shown is suddenly opened, when the colour-producing condensation is produced. These colour phenomena fade rapidly, owing to the differentiation which takes place in the water drops.

The spectroscope shows that when the light is blue there is a general darkening of the whole spectrum, but the absorption is greatest in the red end, and the red end is also much shortened. When the transmitted light was yellow, the blue end was cut out, and the yellow part was much the brightest.

The Cause of the Colour.

In the steam jet when the condensation is dense some of the yellow colour in the transmitted light is due to some of the particles being so small that they reflect and scatter the blue rays. This blue reflected light is polarized. The colours, however, seem in most cases to be produced in the same manner as the colours in thin plates; only a few of the colours of the first order or spectrum are visible, whilst those of the second and third orders are very distinct.

A "Green" or "Blue" Sun.

It is thought that these phenomena give the explanation of the "green" or "blue" sun seen in India and elsewhere in September, 1883, and also on other occasions. The eruption of Krakatão had taken place a few days before the green sun was observed in India. The volcano threw into our atmosphere a great quantity of water vapour, and a vast amount of dust, the very materials necessary for producing a green sun by small drops of water. Prof. C. Michie Smith's observations made in India show that there was a great amount of vapour present in our atmosphere at the time, and most observers frequently refer to a fine form of haze which covered the sky on the days the green sun was seen. It is therefore in the highest degree probable that, under the conditions existing at the time, this haze was greatly composed of water.

A New Instrument for Detecting Dust-polluted Air.

The colour phenomena produced when air is suddenly expanded has led to the construction of a new instrument for indicating roughly the amount of dusty pollution in the air. This instrument has been called a "koniscope," and it is hoped it will be found useful for studying sanitary questions. The instrument consists simply of an air pump and a tube provided with glass ends. The air to be tested is drawn into the tube, where it is moistened and expanded. The depth of colour seen on looking through the tube indicates the amount of impurity in the air. With about 80,000 particles of dust per cubic centimetre the colour is very faint; 1,500,000 gives a fine blue; while 4,000,000 gives an extremely dark blue. These colours are for an instrument having a tube half a metre long. By means of this instrument it is easy to trace the pollution taking place in our rooms by open flames and other causes. We can trace by means of it the pure and impure currents in the room, and note the rate at which the impurity varies.

May 5.—"The Potential of an Anchor Ring." By F. W. Dyson, Fellow of Trinity College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

In this paper the author develops a method of dealing with physical questions connected with anchor rings. He applies it

(1) To find the potential of a solid anchor ring at all external points. The result is obtained in a very convergent series of integrals, each of which may be reduced to elliptic functions. The equipotential surfaces are drawn, when the ratio of the radius of the generating circle to the mean circle of the ring is $\frac{1}{5}$, $\frac{2}{5}$, $\frac{3}{5}$, $\frac{4}{5}$, 1.

(2) The density, at any point, of a ring charged with electricity is found; and the charge is calculated.

(3) The velocity potential of a ring moving in an infinite fluid is found, the kinetic energy calculated, and a few cases of motion discussed.

(4) The annular form of rotating fluid is considered, and the form of the cross-section determined. The cross-section even for large rings is, roughly, of an elliptic shape; the minor axis being parallel to the axis of revolution of the annulus.

May 12.—"On the Embryology of *Angiopteris evecta*, Hoffm." By J. Bretland Farmer, M.A., Fellow of Magdalen College, Oxford. Communicated by S. H. Vines, M.A., F.R.S.

The germination of the spore and the development of the prothallium have been described by Jonkman,[1] who also observed the formation of the sexual organs. The antheridium is formed from a superficial cell of the prothallium, which divides by a wall, parallel to the surface, into an outer shallow cell and an inner cubical cell. The former, by walls at right angles to the free surface, gives rise to the cover-cells; while the inner one, by successive bipartitions, originates the antherozoid mother-cells.

The antheridia are distributed both on the upper and lower surfaces of the prothallium, and apparently without any approach to regularity, though they are somewhat more frequent on the lower surface. I may observe, however, that an antheridium may often occur on the upper surface immediately above an archegonium which has been fertilized.

The archegonia occur exclusively on the lower surface. Their development has been described by Jonkman, who also noticed the division of the neck canal cell, by a transverse wall, into two cells. The division is not, however, invariable, and in one preparation in which the protoplasm had shrunk slightly from the wall, I observed that the cell plate had not extended so as to completely partition the neck passage into two cells.

The oospore, after fertilization, speedily forms an ovoid cellular body, and although I was not so fortunate, owing to scarcity of material, as to see the formation of the earliest cell walls, their succession could be determined with tolerable certainty in the youngest embryo that I met with, consisting as it did of about ten cells.

The basal wall is formed, as in *Isoëtes*, at right angles to the axis of the archegonium. The next one in order of occurrence I believe to be the median wall, which can easily be distinguished, even in advanced embryos, as a well-defined vertical line.

The tranverse wall is much more indefinite, and early loses its individuality owing to the unequal growth of the various parts of the young embryo. The further cell-division is irregular, and to a far greater extent than is the case with the leptosporangiate ferns as described by Hofmeister and Leitgeb.

The anterior epibasal octants together give rise to the cotyledon; the stem-apex is formed, not as in the leptosporangiate ferns, from *one* octant only, but from *both* of the posterior epibasal octants, though one of them contributes the greater portion. The truth of this statement is seen on examining vertical sections through the embryo cut at right angles to the median wall, when a few cells on each side are seen to be clearly marked out, by their dense protoplasmic contents and large nuclei, as meristem cells. There is no single apical cell in *Angiopteris* from which all the later stem tissue is derived, and this fact is, without doubt, to be connected with the character of the apical meristem just described. The root is formed from one of the octants beneath the cotyledon, *i.e.* from an anterior hypobasal one, and is at first indicated by a triangular apical cell, which, in one fortunate preparation, showed the first cap cell. The other octant, together with the two posterior hypobasal octants (which together form the rudimentary foot), round off the base of the embryo. The root presents considerable difficulty in tracing the course of its development, as the apical cell, at no time very clear, is early replaced by two cells. Moreover, the root grows in a somewhat sinuous manner in the embryo, and the cells of its apex may easily be confounded with other triangular cells which occur irregularly scattered in the lower portion of the embryo. It finally emerges, not immediately beneath, nor yet exactly opposite, the cotyledon, but at a distance from it of between one-third and one-half of the circumference of the embryo. The difficulties attending the exact following of its growth, added to the scarcity of the material, have prevented my elucidating completely the details of development, but the important point, that, even before its emergence from the embryo, its apex contains a *group* of initial cells, occupying the place of the single one characteristic of other orders of ferns, can be regarded as established with certainty.

When the embryo has reached a certain size, it bursts through the prothallium; the root boring through below, whilst the cotyledon and stem grow through the upper surface. This manner of issuing from the prothallium at once serves to distinguish *Angiopteris* from those other ferns whose embryogeny is known, and probably the peculiarity of its growth may be reasonably connected with the direction and position of the basal wall which separates the root and short portions of the embryo.

Fresh leaves and roots speedily arise on the young plantlet the second leaf appearing just above the place of exit of the first root—that is, not quite opposite the first leaf. The third leaf rises between the first and second ones, and nearer the first than the second. Their roots observe the same rule of divergence as that which obtains in the case of the first root. The stipular structures, so characteristic of the Marattiaceæ, are entirely absent from the first two leaves, but appear in a well-developed condition on the third and all succeeding leaves.

---

[1] "De geslachtsgeneratie der Marattiaceeën," door H. F. Jonkman.

"On the Shoulder-girdle in Ichthyosauria and Sauropterygia." By J. W. Hulke, F.R.S.

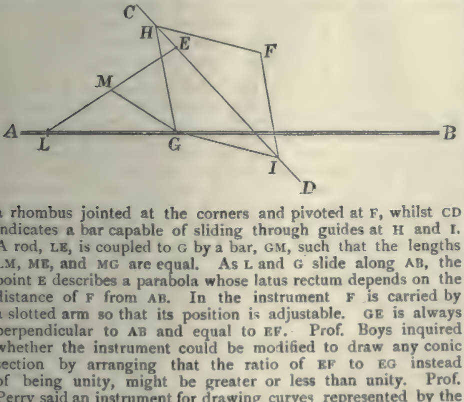
The author discusses the structure of the shoulder-girdle and the homologies of its several parts in these families. He shows that the alleged existence of a precoracoid in the Ichthyosauria rests on an insufficient foundation; offers proofs that in Plesiosauria the anterior ventral ray is not only theoretically but *actually* precoracoid; and also that the dorsal ray in the girdle *is* homologous with the shoulder-blade in Testudinata and other Reptilia.

"On the Development of the Stigmata in Ascidians." By Walter Garstang, M.A.

The author shows that the transverse rows of stigmata, which are present in all the fixed Ascidians, may arise in one or the other of two ways: either as independent perforations, distinct from the first (oozooid of *Clavelina*, buds of *Botryllus*); or as secondary formations, due to the subdivision of a series of primary transverse stigmata on each side (oozooid of *Botryllus*, *Styelinæ*). The former method of development is shown to be a modification of the latter.

The primary transverse stigmata (or "protostigmata") of *Botryllus* and the *Styelinæ* agree precisely with the definitive stigmata of *Pyrosoma* in structure, position, and order of formation. They are accordingly regarded as homologous formations; and the conclusion is drawn that *Pyrosoma* has not been derived from the fixed Ascidians, but represents an ancestral type of Caducichordate Tunicata, antecedent to the whole of the phylum Ascidiacea.

Physical Society, May 13.—Dr. E. Atkinson, Treasurer, in the chair.—Mr. R. Inwards read a paper on an instrument for drawing parabolas. It was designed for drawing curves of short focus such as are required for reflectors and for diagrams of the paths of comets and projectiles. Its construction is based on the fundamental property that every point on the curve is equidistant from the focus and the directrix. In the diagram below, AB is a slot representing the directrix, and FGHI a rhombus jointed at the corners and pivoted at F, whilst CD indicates a bar capable of sliding through guides at H and I. A rod, LE, is coupled to G by a bar, GM, such that the lengths LM, ME, and MG are equal. As L and G slide along AB, the point E describes a parabola whose latus rectum depends on the distance of F from AB. In the instrument F is carried by a slotted arm so that its position is adjustable. GE is always perpendicular to AB and equal to EF. Prof. Boys inquired whether the instrument could be modified to draw any conic section by arranging that the ratio of EF to EG instead of being unity, might be greater or less than unity. Prof. Perry said an instrument for drawing curves represented by the equation $y = x^n$ was greatly needed for engineering work.—Mr. F. H. Nalder exhibited and described some electrical instruments. The first shown was a ballistic galvanometer with one pair of coils, the distinguishing features of which were accessibility, small damping, great sensitiveness, and the arrangement of the control. The control is effected by a "tail magnet" carried on a horizontal tube supported by a pillar outside the case, as suggested by Prof. R. M. Walmsley. A small magnet on the cover serves for zero adjustment. The suspended system consists of four bell magnets, two being in the middle of the coil and one at top and bottom respectively, arranged so as to be astatic. The sensitiveness of the instrument shown was such that ¼ of a microcoulomb gave 300 divisions (fortieths of an inch) when the periodic time was 10 seconds and scale distance about 3 feet. Resistance of galvanometer about 10,000 ohms. To bring the needle to rest quickly, a damping coil mounted on an adjustable stand, and a special reversing key with resistances in its base, are provided. The key has successive contacts arranged so that when pressed lightly, only a weak current passes round the damping coil, whilst when pressed further a much stronger current passes. The strong currents are used to check the large elongations, and the weak ones for finally bringing to zero. A lamp-stand with semi-transparent scale arranged for use with a glow lamp was next shown. Instead of reading by the image of the filament, as is ordinarily done, the lantern is arranged to give a bright disk of light with a black line across the middle. Mr. Blakesley asked if the galvanometer was astatic. For damping non-astatic ones he had found it useful to wind several turns of wire round the bobbin, and put them in series with a few thermo-electric junctions warmed by the hand and a key. In reply, Mr. Nalder said the galvanometer was astatic, but the damping coil could be placed so as to act on one pair of magnets more than on the other. A paper on a portable instrument for measuring magnetic fields, with some observations on the strength of the stray fields of dynamos, by Mr. E. Edgar and Mr. H. Stansfield, was then read. The instrument was described as an inversion of a d'Arsonval galvanometer, for the torque necessary to maintain a suspended coil conveying a constant current parallel to the field gives a measure of the strength of the field. The constant current is furnished by a Hellensen's dry cell which the authors found remarkably constant. The instrument consists of a coil of about fifty ohms, wound on mica and suspended by two German silver strips within a tube. A pointer is fixed to the mica, and a divided head, to which the outer end of one strip is attached, serves to measure the torsion. Within the head chamber is a commutator which automatically reverses the current in the coil when the head is turned in opposite directions from zero. Two readings may thus be taken to eliminate gravity errors due to want of perfect balance in the coil. Means are provided for adjusting and measuring the tension of the suspensions. The constant of the instrument was determined by placing the coil in the field of a Helmholtz galvanometer, and found to be 0·293 per 1°. Any other field is therefore given by $0{\cdot}293\,(n + 1)\theta$, where θ is the angle of torsion in degrees, and n the multiple of 50 ohms in series with the coil. Fields from 2 or 3 C.G.S. lines upwards can be measured to about 2 per cent. by the instrument, and even the earth's field is appreciable. The authors have tested the fields of dynamos at the Crystal Palace Exhibition and elsewhere, and the results obtained are given in the paper. It is noted that the stray fields of multipolar machines fall off much more rapidly than those of two-pole dynamos as the distances are increased, and that near edges and corners of the magnets the fields are much stronger than near flat surfaces. The disturbing effect of armature reactions on the strength of the stray fields were measured, and the shapes of the fields observed in some cases. Experiments on magnetized watches are described in the paper. Mr. Whipple said the Kew Committee were to some extent responsible for the experiments described, for it was on their account that the investigations were commenced. In connection with the rating of so-called non-magnetic watches, it was necessary to know what strength of fields they were likely to be subjected to. The instrument devised for making the tests was a very interesting one, and the results obtained by it of great value. Mr. A. P. Trotter hoped the authors would supplement their work by tracing out the directions of the fields of dynamos, and he described a simple method of doing this by a test needle used as an india-rubber stamp. The question of watches, he thought, must be considered soon; even non-magnetic watches were stopped by being placed in strong fields, owing to Foucault currents generated in the moving parts. Mr. Blakesley inquired whether the instrument could be used in any position. He thought three observations would be necessary to completely determine any field. Mr. Stansfield, in reply, said they used a pilot needle for showing the directions of the fields, and then placed the coil accordingly. The instrument could be used in any position, for the weight of the coil was only about 2 grammes, and did not greatly alter the tension of the suspensions, which was usually about 300 grammes. A watch with a brass balance was not influenced by a field of 10 C.G.S. lines but seriously affected by one of 40.—Mr. Joseph W. Lovibond read a paper on a unit of measurement of light and colour. The paper was illustrated by many coloured charts, diagrams, and models, and several pieces of apparatus by which colour measurements could



be made were shown. The principle of the measurements depends on the selective absorption of the constituents of normal white light by coloured glasses (red, yellow, and blue). The depths of tint of the glasses are carefully graduated to give absorptions in numerical proportions. For example, two equal glasses, each called one-unit red, give the same absorption as a two-unit red, and so on. The units of red, yellow, and blue are so chosen that a combination of one of each absorb white light without colouring the transmitted light. Such a combination is called a "neutral tint unit." By the use of successive neutral tint units, white light can be gradually absorbed without showing traces of colour, and the number of such units required to produce complete absorption is taken as a measure of the intensity or luminosity of the white light. Methods of representing colours by circles and charts were fully dealt with, and the influence of time of observation on the penetrability of different colours was illustrated by diagrams. The results of 151 experiments on colour mixture were explained, and represented diagrammatically. After the reading of the paper the methods used for colour matching and measurement were shown by Mr. and Miss Lovibond.—Mr. R. W. Paul exhibited his improved form of Wheatstone bridge, arranged to occupy the same space, and fulfil the same conditions, as the well-known Post Office pattern.

Chemical Society, April 21.—Prof. A. Crum Brown, F.R.S., President, in the chair.—The following paper was read:—Masrite, a new Egyptian mineral, and the possible occurrence of a new element therein, by H. D. Richmond and Hussein Off. Masrite is the name assigned by the authors to a variety of fibrous alum obtained in Egypt by S. E. Johnson Pasha. It contains from 1 to nearly 4 per cent. of cobalt. This being the first occasion on which cobalt has been met with in Egypt, the authors were led to inquire whether the blue colour used in the paintings on Egyptian monuments contained that element. The samples obtained, however, owed their colour to compounds of copper and iron. The mineral is principally interesting on account of the presence in it of a minute quantity of a substance, the properties of which appear to be unlike those of any known element, which the authors provisionally term masrium, from the Arabic name for Egypt. From an analysis of the oxalate, on the assumption that it is a bivalent element, the atomic weight of masrium is calculated to be 228. The authors point out that there is a vacant place in the glucinum-calcium group of the periodic system for an element having the atomic weight 225. In many of its properties masrium resembles glucinum, and the oxalate is analogous to that of calcium. Masrite has the composition

$$(Al,Fe)_2O_3, (Ms,Mn,Co,Fe)O, 4SO_3, 20OH_2.$$

May 5.—Prof. A. Crum Brown, F.R.S., President, in the chair.—An extract was read from a letter to Sir H. E. Roscoe, written by Prof. Kühne, of Heidelberg, at the request of Prof. Bunsen, expressing his thanks for the address presented to him by the Chemical Society.—The following papers were read:—The existence of two acetaldoximes, by W. R. Dunstan and T. S. Dymond. Acetaldoxime, $CH_3 . CH : NOH$, has hitherto been regarded as a liquid capable of existing in only one form, attempts to obtain evidence of the existence of an isomeride having failed; the authors, however, find that it can be crystallized by cooling. The crystals so obtained are often several inches in length, and melt at 46°·5. On heating them to 100°–150° no decomposition occurs, and the substance boils constantly at 114°·5. If this heated liquid be now cooled, it does not crystallize until nearly 35° below the melting-point of the original substance, and the crystals so obtained become liquid at ordinary temperatures. Many similar observations have been made, and it has been invariably found that on heating the aldoxime the freezing-point is lowered to a greater or less extent. Evidence has in this way been accumulated, showing that a change in the constitution of acetaldoxime occurs when it is heated, the original substance, melting at 46°·5, being gradually converted into a new modification, which melts at 12°. It is noteworthy that the acetaldoxime melting at 12° is slowly reconverted into that melting at 46°·5 on standing at ordinary temperatures. The authors term the substance melting at 46°·5 α-acetaldoxime, that melting at 12° being named β-acetaldoxime.—Sulphonic acids derived from anisoils (No. i.), by G. T. Moody. The author finds that contrary to the statement of Kekulé, and of Opl and Lippmann, anisoil and phenetoil afford only parasulphonic acids on sulphonation. Carefully purified anisoil was dissolved in concentrated sulphuric acid, and the product poured into water, when part of the anisoil was liberated, showing that as in the case of phenol an intermediate compound is formed before the sulphonic acid. The anisoil thus set free was treated with strong sulphuric acid at 80°, when complete sulphonation occurred. The solution yields a well-defined calcium salt; no indications of the presence of an isomeride were found. The calcium, potassium, and sodium salts of the anisoil parasulphonic acid obtained in this way are described, together with the sulphochloride and sulphonamide. Pure phenetoil similarly is shown to yield only the parasulphonic acid. The products of sulphonation, either with sulphuric acid or with chlorosulphonic acid, are in both cases the same, only one sulphonic acid resulting.—The formation of trithionate by the action of iodine on a mixture of sulphite and thiosulphate, by W. Spring. In his paper on the investigation of the change proceeding in an acidified solution of sodium thiosulphate, Colefax credits the author with having stated that trithionate of sodium is produced when iodine acts on a mixture of sodium sulphite and thiosulphate, and further denies that this is the case. The author used potassium salts, and not sodium salts, but, owing to an error in the abstract of Spring's original paper, Colefax was led to believe that sodium salts were used. The difference in the behaviour of the potassium and sodium salts is very striking, and arises from the greater instability of the sodium polythionates already pointed out by the author. Another difference between the two sets of experiments is found in the employment by Colefax of a larger proportion of iodine than that used by the author. The equation

$$K_2SO_3 + K_2S_2O_3 + I_2 = K_2S_3O_6 + 2\,KI$$

requires less iodine than would be necessary to oxidize the sulphite to sulphate, and the hyposulphite to tetrathionate of sodium. The author does not, however, contend that the formation of trithionate takes place in accordance with the equation

$$Na_2S_2O_3 + Na_2SO_3 + I_2 = Na_2S_3O_6 + 2NaI.$$

He is convinced that sulphites have the property of desulphurising the tetrathionates, so as to convert them into trithionates. It would hence be more consistent to admit that the sodium sulphite which owes its existence to the employment of a reduced quantity of iodine decomposes the small quantity of sodium tetrathionate produced in the first instance, thus,

$$Na_2S_4O_6 + Na_2SO_3 = Na_2S_3O_6 + Na_2S_2O_3.$$

The statement erroneously ascribed by Colefax to the author seems, in consequence, to be really correct. It is, however, indispensable that the experiments should be performed under exactly the same conditions as those employed in the work on the potassium salts.—The determination of the temperature of steam arising from boiling salt solutions, by J. Sakurai. The evidence now on record as to the temperature of the steam arising from boiling salt solutions is exceedingly unsatisfactory and inconsistent. Such being the case, the author has devised a method for accurately measuring this temperature, and finds that the temperature of the steam escaping from a boiling salt solution is the same as that of the solution. The conditions for success are:—(1) The thermometer used must be kept from contact even with the smallest drops of the solution thrown up by ebullition. (2) The effect of cooling of the thermometer by radiation must be rendered insignificant in proportion to the heating up by the steam. This condition is readily fulfilled by the expedient of combining the introduction of steam from without with the ebullition by the lamp. (3) The walls of the chamber surrounding the thermometer must be sufficiently protected from external cooling, and yet, at the same time, must not be heated to the temperature of the steam. This is effected by jacketing the steam chamber with the vapour evolved from dilute acetic acid boiling at about 2° lower than the salt solution. The agreement between the numbers representing the temperature of the steam and that of the boiling salt solution is good.—Note on an observation by Gerlach of the boiling-point of a solution of Glauber's salt, by J. Sakurai. Some years ago Gerlach stated that the steam escaping from a boiling solution of Glauber's salt containing a crystalline magma of the anhydrous salt indicates a temperature of 100°, whilst the liquid is boiling at 82° or even 72°. The author finds that this is hardly true, for it is only a wet mass of sodium sulphate crystals that is heated. The steam, consequently, does not arise uniformly from the heated mass, but escapes from channels produced in those portions of it which are in contact with the sides of the vessel. The central portion of the magma therefore may be at a low temperature, whilst steam at 100° is issuing from the sides.—Chemistry of the thioureas, Part ii., by E. A. Werner. It is pointed out that the paper recently published by Bertram on the monophenylthioureas was evidently written in ignorance of the fact that the bulk of the work detailed therein has been already published by the author. A number of new derivatives of thiourea are now described.

Geological Society, May 11.—W. H. Hudleston, F.R.S., President, in the chair.—The President announced that a bust of the late Sir Charles Lyell had been kindly presented to the Society by Mrs. Katherine Lyell, through the intermediary of Prof. J. W. Judd, F.R.S.—The following communications were read:—On the so-called gneiss of Carboniferous age at Guttannen (Canton Berne, Switzerland), by Prof. T. G. Bonney, F.R.S. It is stated by Dr. Heim (*Quarterly Journal*, vol. xlvi. p. 237) that the stems of *Calamites* have been found at Guttannen in a variety of gneiss, *i.e.* in one of a group of rocks which exactly "resemble true crystalline schists in mode of occurrence. Petrographically they are related to them by passage rocks; at least the line of separation is not easily distinguished. . . . The Palæozoic formations mostly show an intimate tectonic relation to the crystalline schists, and have been converted petrographically into crystalline schists." The Author describes the result of a visit to the section at Guttannen in company with Mr. J. Eccles (to whom he is greatly indebted for kind assistance), and of his subsequent study of the specimens then collected. The belt of sericitic "phyllites and gneisses," presumably of Carboniferous age, represented on the Swiss geological map (Blatt xiii.) as infolded, at and above Guttannen, in true crystalline gneissoid rocks, is found on examination to consist partly of true gneisses, partly of detrital rocks. The boulder from which the stems in the Berne Museum were obtained belongs to the latter. These rocks sometimes present macroscopically, and occasionally even microscopically, considerable resemblance to true gneisses, but this proves on careful examination to be illusory. They are, like the Torridon Sandstone of Scotland, or the *Grès feldspathique* of Normandy, composed of the detritus of granitoid or gneissoid rock, which sometimes forms a mosaic resembling the original rock, and which has been generally more or less affected by subsequent pressure and the usual secondary mineral changes. Thus, if the term be employed in the ordinary sense, they are no more gneisses than the rocks of Carboniferous age at Vernayaz (Canton Valais) are mica-schists, but in some cases the imitation is unusually good, and, so far as the author saw, there are at Guttannen neither conglomerates nor slates to betray the imposition, as happens at the other locality. The reading of this paper was followed by a discussion, in which the President, Prof. Judd, Mr. Eccles, General McMahon, Mr. Rutley, Prof. Blake, Prof. Bonney, and Prof. Seeley took part.—On the lithophyses in the obsidian of the Rocche Rosse, Lipari, by Prof. Grenville A. J. Cole, and Gerard W. Butler. The rock described in this paper differs in no essential particular from that at Forgia Vecchia, or from the obsidian on the north flank of Vulcano; but the specimens show in a specially striking manner the passage through various stages of lithophysal structure, from indisputable steam-vesicles with glassy walls to typical solid spherulites. A full description is given of the formation of spherulites by a double process—firstly, divergent growth from the margins of vesicles outwards, and secondly, convergent growth inwards from the margins towards the centres of the hollows, until in the smallest cases the fibres from the opposite sides of the vesicle may meet in the centre, producing a spherulite, which, but for the occurrence of intermediate stages, might be supposed to have originated entirely by divergent growth. The authors give details of the appearances presented by intermediate stages of growth. The prevailing type of spherulite, both in Lipari and Vulcano, shows in section a dusky fibrous central area, which may possess concentric as well as radial structure, surrounded by an irregular brown cloudy zone of various width. The authors' studies lead them to the conclusion that this type owes its characters to the dual mode of growth, and therefore to the original presence of vesicles in the rock. Commonly the process of infilling does not go so far as this; on the ends of the felspar fibres plates of tridymite are deposited, and this seems to close the growth. It is clear that the lithophysal structure of the Lipari obsidians was formed during the cooling of the mass, and not by subsequent amygdaloidal infilling of vesicles. The authors discuss the effect of confined vapours on such rocks as those forming the subject of the paper, noting that these vapours may be kept at a high temperature for a considerable time, each vesicle thus becoming a sphere of hydrothermal action; so that if the surrounding glass remains at a temperature little below its fusion-point, crystallization will be promoted in it, and at the same time the action of the vapour in the vesicle will produce reactions on its walls. An appendix, by Prof. Cole, treats of the lithophyses and hollow spherulites of altered rocks. While admitting the presence of true lithophyses in many of the Welsh lavas, he is not prepared to abandon a former suggestion that the interspaces between successive coats of the Conway lithophyses result from alteration of a formerly solid mass. In the lavas of Esgair-felen and near the Wrekin he has no doubt as to the production of "hollow spherulites" by ordinary processes of decay. The typical Continental pyromerides are truly spherulitic, as is much of the Wrekin lava. In the latter case and that of the rocks of Bouley Bay it will be difficult to distinguish between infilled primary and secondary cavities. In the discussion which followed the reading of this paper Prof. Bonney, Prof. Judd, General McMahon, Mr. J. W. Gregory, Mr. Rutley, Prof. Cole, and Mr. G. W. Butler took part.

Royal Meteorological Society, May 18.—Dr. C. Theodore Williams, President, in the chair.—The following papers were read:—Raindrops, by Mr. E. J. Lowe, F.R.S. The author has made over 300 sketches of raindrops, and has gathered some interesting facts respecting their variation in size, form, and distribution. Sheets of slate in a book form, which could be instantly closed, were employed; these were ruled in inch squares, and after exposure the drops were copied on sheets of paper ruled like the slates. Some drops produce a wet circular spot, whilst others, falling with greater force, have splashes around the drops. The same sized drop varies considerably in the amount of water it contains. The size of the drop ranges from an almost invisible point to that of at least 2 inches in diameter. Occasionally large drops fall that must be more or less hollow, as they fail to wet the whole surface inclosed within the drop. Besides the ordinary raindrops, the author exhibited diagrams, showing the drops produced by a mist floating along the ground, and also the manner in which snow-flakes, on melting, wet the slates.—Results of a comparison of Richard's anémo-cinémographe with the standard Beckley anemograph at the Kew Observatory, by Mr. G. M. Whipple. This instrument is a windmill vane anemometer, and is formed by six small wings or vanes of aluminium, 4 inches in diameter, inclined at 45°, rivetted on very light steel arms, the diameter of which is so calculated that the vane should make exactly one turn for a metre of wind. Its running is always verified by means of a whirling frame fitted up in an experimental room, where the air is absolutely calm, and, if necessary, a table of corrections is supplied. The recording part of the apparatus differs entirely from any other anemometer, and is called the anémo-cinémographe, and in principle is as follows:—The pen, recording on a movable paper, is wound up at a constant rate by means of a conical pendulum acting as a train of wheel links, whilst a second train, driven by the fan, is always tending to force it down to the lower edge of the paper; its position, therefore, is governed by the relative difference in the velocity of the two trains of wheel-work, being at zero when the air is calm, but at other times it records the rate of the fan in metres per second. The author has made a comparison of this instrument with the standard anemometer at the Kew Observatory, and finds that it gives exceedingly good results.—Levels of the River Vaal at Kimberley, South Africa, with remarks on the rainfall of the watershed, by Mr. W. B. Tripp. Measurements of the height of the River Vaal have for several years past been made at the Kimberley Waterworks. These gaugings having been placed at the disposal of the Society, the author has compared them with the rainfall of the watershed. There is a marked period of floods and fluctuations at a comparatively high level from about the end of October to the latter part of April, and a period of quiescence during which the river steadily falls, with very slight fluctuations from about April 19 to October 31. The highest flood (52·5 feet) occurred in 1880, the next highest being 50·3 feet on January 24, 1891.

OXFORD.

University Junior Scientific Club, May 4.—The meeting was held in the University Museum. In private, business regulations about the "Robert Boyle Lecture" were passed by the Club.—Papers were read on the action of light on metallic iodides, by Mr. Douglas Berridge; on the colours of birds, by Mr. F. Finn; and on Caliche, by Mr. P. Elford.

May 13.—At an open meeting Mr. E. F. im Thurn (Exeter) delivered a lecture on "Primitive Games of the Red Men of Guiana." Prof. Tylor afterwards addressed the Club.—The inaugural "Robert Boyle Lecture" will be given at a *conversazione* on May 27. All old members of the Club are cordially invited.

PARIS.

Academy of Sciences, May 16.—M. d'Abbadie in the chair.—Contribution to the history of silico-carbon compounds, by M. P. Schutzenberger. The compound, SiC, has been produced by long heating of silicium diluted with silica in carbon crucibles. The friable mass is broken up, heated with potash solution, which dissolves out the silicium, and some silica, and then boiled with moderately concentrated hydrofluoric acid, by which all the silica is taken up and silicium nitride is converted into silicium fluoride and ammonium fluoride. The clear green pulverulent residue of SiC is not attacked by potash or by boiling HF; it is infusible, and at a white heat forms SiCO.—On the determination of the density of liquefied gases and their saturated vapours; elements of the critical point of carbonic acid, by M. E. H. Amagat. The critical constants for carbonic acid are given as—temp. = 31°·35 C., pressure = 72·9 atmos., density = 0·464.—Observation of the partial eclipse of the moon on May 11–12, 1892, by MM. Codde, Guérin, Nègre, Zielke, Valette, and Léotard.—On the theory of *fonctions fuchsiennes*, by M. L. Schlesinger.—On the relations existing between the infinitesimal elements of two reciprocal polar surfaces, by M. Alphonse Demoulin.—On transformations in mechanics, by M. Paul Painlevé.—The physiological scale of distinct vision, applications to photometry and *photo-esthésiométrie*, by M. W. Nicati.—On a method of separation of xylenes, by M. J. M. Crafts.—Calculation of boiling-points of compounds with simple terminal substitution, by M. G. Hinrichs.—Method for the proximate analysis of chlorophyll extracts; nature of chlorophyllane, by M. A. Étard.—Influence of the nature of the soil on vegetation, by M. J. Raulin.—Presence of fumarine in one of the Papaveraceæ, by M. J. A. Battandier.—On some muscular anomalies in man, by M. Fernand Delisle.—On the apparently teratological origin of two species of *Triclades*, by M. P. Hallez.—On the theory of gills and the parablast, by M. F. Houssay.—The origins of the wing nerve among the Coleoptera, by M. Alfred Binet.—The nervous system of *Nerita polita*, by M. L. Boutan.—On the origin and formation of the chitinous coat of the larvæ of *Libellules*, by M. Joannes Chatin.—On the microscopic structure of ooliths from the *bathonien* and *bajocien* of Lorraine, by M. Bleicher.—The odoriferous properties of alcohols of the fatty series, by M. Jacques Passy. The odoriferous power, as measured by the inverse of the millionths of a gram present in one litre of air when the odour can be just distinguished, increases regularly with the molecular weight.—On the lack of movement of the deep oceanic waters, by M. J. Thoulet.

BERLIN.

Physiological Society, April 27.—Prof. du Bois-Reymond, President, in the chair.—Dr. Boruttau gave an account of experiments made to determine the cause of the difference in latent period observed during the direct and indirect stimulation of muscles, being, as is well-known, greater (with maximal and supra-maximal stimuli) in the latter mode of stimulation. According to some observers the difference is due to the resistance offered by the end-plates, whereas some regard it as due rather to a summation of stimuli during direct stimulation. The speaker had satisfied himself by a careful repetition of the experiments under many varying conditions that the difference is due solely to the resistance of the end-plates. In connection with the above, Prof. Gad pointed out the possible important bearing of the results obtained on the processes which go on in other organs. Thus recent anatomical research has shown that in the central nervous system there is no complete continuity between the axis-cylinders and ganglia, hence the existence of some intermediate structure must be assumed, and a portion at least of the slowing which impulses experience in the central nervous system may be due to the resistance offered by this structure.—Prof. Wolff exhibited a patient in whom the larynx had been completely extirpated some seven months previously, and who was now able, by means of an artificial larynx, to speak quite loud and clearly. Prof. Gad gave an historical account of the construction of artificial larynxes, of the requirements which these instruments must satisfy, and of recent improvements in the cannulæ employed by patients.

Physical Society, May 6.—Prof. Kundt, President, in the chair.—Dr. Gross spoke on the principle of entropy, and criticised several formulæ of Clausius and Zeuner.

THE GRAMMAR OF SCIENCE.

The Grammar of Science. By Karl Pearson, M.A., Sir Thomas Gresham's Professor of Geometry. "The Contemporary Science Series." (London: Walter Scott, 1892.)

ONE chief merit of this book is its exposition of the meaning of scientific law. There still exists, unfortunately, a type of mind which delights in such phrases as "the reign of law," the "immutable laws of Nature," and so on. The truly scientific mind has, however, been long familiar with the truth that a so-called law of Nature is simply a convenient formula for the co-ordination of a certain range of phenomena. It is this which Prof. Pearson so emphatically, if somewhat redundantly, expounds in the earlier chapters of the "Grammar." As he delights in putting it, a scientific law is a description in mental shorthand of certain sequences of sense-impressions. Through these sense-impressions alone can we gain any knowledge of what we are accustomed to call the external world. Thus the Universe as pictured by the scientific mind is a purely mental product. We can assert, scientifically, nothing regarding its constitution other than what we may validly infer from our perceptions and the conceptions based on these; and even then we must never forget that the reality to us is conditioned wholly by our powers of perception. This is the grand argument of the grammarian of science.

In developing his theme he introduces not a few interesting questions and analogies. Take, for example, his comparison of the brain to a telephone exchange. Here Reason, presiding as clerk, finds by experience that a certain subscriber always desires to correspond with a certain other subscriber. As soon as the call-bell from the former sounds, the clerk mechanically links him to the latter. "This corresponds to an habitual exertion following unconsciously on a sense-impression." Other analogies are obvious. Now, just as the clerk would obtain a very scrappy knowledge of the outside world if he had to trust simply to the messages which stream past him through the exchange, so (it is suggested) the picture our mind forms of the external world acting upon us through our sense-impressions may be very wide of the reality. Of course analogies must not be pressed too far. Yet it does seem that this analogy of the telephone exchange could be worked out most consistently by the despised teleologist. To Sir Thomas Gresham's Professor of Geometry, however, a telephone exchange evolving its own clerk is as simple a matter as an uninterrupted stream of sense-impressions creating Spencerianly a consciousness.

But Prof. Pearson is no mere preacher of familiar doctrines. He is a second Hercules, self-appointed to clear the scientific stables of all materialistic and metaphysical rubbish. He labours at the task of proving how illogical is the mind that passes to "the beyond" of the sense-impressions and the conceptions directly based on these. Thus he argues that, because the Universe is known only as our own mental product, we have no right to infer a mind in or above Nature as an explanation of the universality of the scientific law. Nevertheless, it behoves him to find a rational substitute for the law of continuity on which the authors of the Unseen Universe build their edifice. Consequently on p. 121 we read:—

> "It is therefore not surprising that normal human beings perceive the same world of phenomena, and reflect upon it in much the same manner."

Why not surprising? Because, as we learn from the preceding sentence, human beings "in the normal civilized condition have perceptions and reflective faculties nearly akin." But why nearly akin? Well, it has to be so because "the world of phenomena must be practically the same for all normal human beings," or the universality of scientific law will fail. Putting in the definitions of the terms in the first quoted sentence we read:—It is therefore not surprising that beings, who have perceptive and reflective faculties capable only of producing practically the same world of phenomena, perceive the same world of phenomena and reflect upon it in much the same manner. In this exquisite cycle of reasoning what, we ask, is the logical work done?

Our grammarian poses as a logician of the straitest sect. Bad logic he cannot abide; and since apparently he cannot read a book without seeing the cloven hoof he must have rather a sorry time of it. His own logic must, of course, be flawless. So, when we are told with reiterated emphasis that time and space are but modes of perception, and are then asked to imagine our Universe in time and space without a consciousness to perceive it, we feel a sinking at the heart. Things, we find, can exist under certain modes of a non-existent perception. The laws of Nature are a mental product; yet a certain evolution theory logically based upon them quite eliminates the mental. We are reminded of the sagacious carpenter who sat high and lifted up on the end of the bracket beam he was sawing through; or of the small boy who spent his wealth in buying a purse to hold it in.

A large section of Prof. Pearson's book is destructive criticism. "Cause," "Force," and "Matter" are as red rags to him. Cursed be he who uses these words without clearly defining, in footnote or otherwise, their significance according to the definitions given in the "Grammar of Science." Sir Isaac Newton is severely visited for his sins; Thomson and Tait get a thorough drubbing; Maxwell is censured for his bad logic; and Prof. Tait especially, if we are to judge of him through the medium of this book, must have done more to retard the progress of science than any other single man of the century. Sound criticism is always welcome; but "smart" controversy of the hustings type is rarely sound in print. As a fair example of our grammarian's method, take his critique of Maxwell's descriptions (not definitions be it noted) of the intimate relation between matter and energy. Maxwell says, "We are acquainted with matter only as that which may have energy communicated to it from other matter, &c.," and "Energy, on the other hand, we know only as that which . . . is continually passing from one portion of matter to another." These are represented as meaning that "the only way in which we can understand matter is through the energy which it transfers," and "the only way to understand energy is through matter. Matter has been defined in terms of energy, and energy again in terms of matter." By what logic or grammar can *understand* be substituted for *are acquainted with* or *know;* and by what right is a description twisted into a definition? Words in their usual meanings may, however, be of little consequence to a writer who persists in using the English word *resume* in the French sense. It seems to us that Prof. Pearson has altogether missed the significance of the word "objective" as used by Prof. Tait, to whom, as everyone knows or should know, we owe the first clear presentation of the dogma that force has no objective existence. At any rate, we are surprised to find in the "Grammar of Science" no distinct reference to the two grand principles of all science—to wit, the conservation of matter and the conservation of energy. This omission by an avowed writer on the principles of science is certainly matter of surprise. As regards the views of force expounded in the book, the author is simply a disciple of Prof. Tait. If not, he must regard Tait as "that worst of plagiarists"—the man who made the discovery before he did. Prof. Pearson has, indeed, a certain fatality for having dealings with that most unsatisfactory kind of plagiarism. In Tait's "Properties of Matter," first edition (1885), paragraph 162, are written these words :—

> "Sir W. Thomson has shown that if space be filled with an incompressible fluid, which comes into existence in fresh quantities at the surface of every particle of matter, at a rate proportional to its mass, and is swallowed up at an infinite distance, or, if each particle of matter constantly swallows up an amount proportional to its mass, a constant supply being kept up from an infinite distance,—in either case gravitation would be accounted for."

If this is not *essentially* the theory of "ether-squirts" which "the author has ventured to put forward," what then is the ether-squirt? The quotation just given occurs in Tait's seventh chapter, which, being empty of "red rags," probably failed to come within Prof. Pearson's sphere of perception.

Be it noted that we do not criticize our author's views as to the significance of such words as force and cause; but we cannot say we fancy his critical tone towards others. He himself uses the phrase "acceleration of A due to B," but warns the reader in a footnote against taking the phrase in its literal sense; yet anybody else from Newton down the centuries who has dared to use similar phrases is sneered at as a searcher after the unknowable "why."

For example, in his criticism of Newton's first law of motion, what right has he to say that Newton "was thinking of force in the sense of mediæval metaphysics as a cause of change in motion"? What is the perceptual or conceptual basis of this assumed certitude? Newton was probably thinking of *vis impressa*, the very grammatical form of which shows that there was nothing ultimate implied in the *vis*. After discussing the various kinds of *vires* that have to be dealt with, and pointing out clearly by definitions and descriptions their precise meanings, Newton concludes one paragraph in these words :—

> "*Mathematicus duntaxat est hic conceptus: Nam virium causas et sedes physicas jam non expendo.*"

Then a little further on we read :—

> "*Has vires non physice sed mathematice tantum considerando. Unde caveat lector, ne per hujusmodi voces cogitet me speciem vel modum actionis causamve aut rationem physicam alicubi definire vel centris* (*quæ sunt puncta mathematica*) *vires vere et physice tribuere; si forte aut centra trahere, aut vires centrorum esse dixero.*"

Can it be that Prof. Pearson has never read Newton's "Principia," and has he forgotten that the complete title is "Philosophiæ Naturalis Principia Mathematica"? To insinuate that Newton's laws of motion (which, it should never be forgot, are intimately associated with the *Definitiones*) are incomplete because they may not possibly apply to corpuscles other than those of "gross" matter, to corpuscles of all imaginable types in short, implies a complete misapprehension of the whole purpose and scope of the "Principia." Again, our grammarian pounces upon the word "body," or *corpus*, as used by Newton, who should at least have used particle or corpuscle. In Definition I. will be found the meaning intended by Newton to be attached to the word *corpus;* but in any case the whole phraseology of the first law is quite intelligible to the candid mind. Newton had a fine faith in his reader. He gave the *Definitiones* and *Axiomata* in a form that appealed at once to the common experiences of thoughtful minds; and what more do we need?

Prof. Pearson characterizes the second law as a "veritable metaphysical somersault. How the imperceptible cause of change in motion can be applied in a straight line surpasses comprehension, &c." This may be smart, but is it relevant? Where does Newton define *Vis Motrix* as the "imperceptible cause of change in motion"?

We have not space to enter upon a discussion of the five laws of motion suggested by Sir Thomas Gresham's Professor of Geometry as a true non-metaphysical basis for all science. They are good enough in their way; but they seem to lack that direct reference to ordinary facts of experience which is a desideratum of all physical axioms. They begin with a dance of molecules and end with a measure of force Their ostensible merits are their logical form and their comprehensiveness—ether corpuscles as well as matter corpuscles being nominally included. Yet we have to confess our inability to see that these laws of motion can effect more than Newton's. Dynamics, in all its branches, still is Newtonian.

In its discussion of the meaning of scientific law, in its presentation of kinematic principles, and in its treatment of certain present-day speculations as to the constitution of matter and of ether, Prof. Pearson's book is at once interesting and instructive. There is much in it fitted to arrest the materialistic tendency of many who are devotees of science to the exclusion of all other intellectual activities. Yet its own conclusions are as materialistic as they well can be. The automaton theory of the human will, and the spontaneous generation of life, are articles of its creed. In the second last chapter we are treated to a choice collection of charming dogmatisms. Perhaps the most charming of all is the author's "unwavering belief" that the hitherto undiscovered formulæ which are to make history a science "can hardly be other than those which so effectually describe the relations of organic to organic and of organic to inorganic phenomena in the earlier phases of their development." A curious assertion, surely, for one to make who objects to Newton's laws of motion because they don't include imaginable but still unknown types of corpuscular motion. The particular value, however, of this confession of faith is that it enables the confessor to convict of scientific heresy Prof. Robertson Smith and all others who cannot regard it as other than an assumption. To believe as Prof. Pearson believes is to believe scientifically; all other belief is rotten. As the "auld licht" dame said when telling over the number of the elect, "Ay, there's jist me and John; and whiles I'm no that sure o' John." C. G. K.

THE TEACHING OF THE PRINCIPLES OF CHEMISTRY.

Laboratory Practice: A Series of Experiments on the Fundamental Principles of Chemistry. A Companion Volume to "The New Chemistry." By Josiah Parsons Cooke, LL.D., Erving Professor, and Director of the Chemical Laboratory, Harvard University. Pp. 192. (London: Kegan Paul, Trench, Trübner, and Co., 1892.)

THIS little book represents another attempt to teach the theory of chemistry upon the basis of a narrowly restricted experience of facts and phenomena. Whether this is possible is a question debatable, and still, in fact, debated among teachers. That it is possible to make the study of chemistry by young people, as a form of intellectual exercise, more useful than has usually been the case there can be no doubt, and that much instruction could be got out of a course such as this which is indicated in Prof. Cooke's little work is certain. The book appears to be intended as a guide for the teacher as much as for the pupil, and much would depend upon the qualifications of the former for the work of demonstration and exposition. It contains directions for the performance of a system of experiments; and to do justice to the system the teacher ought carefully to study the instructions given in the introduction, and to act upon them. And to those who know anything of the manner in which chemistry is too often taught in the schools of this country, either by the visiting "science teacher," who knows little, or by the mathematical master, who usually knows nothing at all about the subject, such remarks as the following, taken from the introduction, will seem particularly welcome and appropriate.

The author says:

> "Experiments are only of value as parts of a course of instruction logically followed out from beginning to end. In such a course there must be necessarily a great deal to be filled out by the teacher, and this can vastly better be taught from his lips, with such illustrations as he can command, than from any books."

And again,

> "The best apparatus will be of no use unless the teacher stands before it and speaks to his pupils out of the fulness of his own knowledge. This is an essential condition of success, and without it the experimental method should never be attempted."

But after these things have all been duly noted and acted upon, a glance at the table of contents is apt to raise a doubt whether after all the erection of so large a superstructure is justifiable or practicable upon foundations so slender. The book begins at p. 13, and thence to p. 52, with the exception of three or four pages about water, the whole is devoted to the physical properties of liquids and solids represented by water and air. Then we come to oxygen, hydrogen, sulphur and its oxides, chlorine, carbon and the oxides of carbon, ethylene, nitrogen, nitric acid, ammonia, magnesium, zinc, sodium, copper, and iron, all of which are included in the fifty pages following. Then comes a chapter on general principles, a third on molecules and atoms, followed by chapters on symbols and nomenclature, molecular structure, and thermal relations.

This is not the first book which has appeared with similar objects. In this country there have been Prof. Ramsay's little book on "Chemical Theory," Muir and Carnegie's "Practical Chemistry," Shenstone's "Practical Introduction to Chemistry," and probably others, which seem to aim at dealing with chemistry in the same kind of way, which is intended to be a way of pleasantness and a short cut to rather exalted territory. The road, however, is bordered by precipices unseen by the young traveller.

The advocates of this kind of system, which consists in passing from one or two rough experiments, or observations, direct to great generalizations, anticipate great things from its general adoption. All the rising generation who come under its influence are to possess greatly developed powers of observation and reasoning. Some of those who have been accustomed to old-fashioned ways of getting a good grip of facts, and some stock of experience before proceeding to difficult investigation, are not convinced, and are inclined to doubt whether school boys and girls can be made to reason out for themselves problems which have cost for their elucidation the work of generations of men. And the logic of the process is often more than questionable. Here is an example (p. 110). The law of the conservation of mass is supposed to be established by a single experiment, which consists in burning a bit of phosphorus in a jar, and showing that there is no loss of weight.

> "Hence it must be that, *The sum of the weights of the products of a chemical change is exactly equal to the sum of the weights of the factors.* We may conceive of any chemical process as taking place in an hermetically sealed space—indeed the earth is essentially such a space—and hence this law must be universally true."

Here the process of induction is reduced to collecting a single instance, which is itself imperfect. Surely this is not to stand as an example of the methods of physical science.

One would not wish to be hard upon Prof. Cooke's little book, but with many meritorious features it does not seem to represent a great improvement upon the books referred to above. The naïve statement at the end of the introduction, that the directions can in many cases be improved, cannot be held to excuse the rough and slipshod character of some of the forms of experiment recommended. The book will supply suggestions which will be found useful by some teachers, but the reference to apparatus unfamiliar on this side the Atlantic may be a slight bar to its adoption here. W. A. T.

OUR BOOK SHELF.

Elementary Geography of the British Colonies. By George M. Dawson, LL.D., F.R.S., and Alexander Sutherland, M.A. With Illustrations. (London: Macmillan and Co., 1892.)

THIS volume forms one of the well-known geographical series edited by Sir Archibald Geikie. The part of it for which Dr. Dawson is responsible is that which deals with the British possessions in North America, the West Indies, and the southern part of the South Atlantic Ocean. Mr. Sutherland describes the British colonies, dependencies, and protectorates in the northern part of the South Atlantic, Mediterranean Sea, Africa, Asia (exclusive of India and Ceylon, which are described in a separate volume of the series, by Mr. H. F. Blanford), Australasia, and Oceania. Both writers have enlightened ideas as to the needs of those for whom such books are prepared. They have carefully avoided the bringing together of masses of uninteresting detail, their chief object being to convey a good general idea of the physical features and resources of the British colonies, and of the various ways in which these have affected the distribution of the population and the growth of industry and commerce. The facts are presented simply and clearly, and every page contains statements which an intelligent teacher would have no difficulty in using as texts for pleasant and profitable instruction. Most of the illustrations are from photographs, but there are also several very effective engravings from original drawings by Mr. Pritchett.

Farmyard Manure. By C. M. Aikman, M.A., B.Sc. (Edinburgh and London: Blackwood, 1892.)

WE are told in the preface that this little work is in substance a chapter from a larger work on "Soils and Manures," on which the author is at present engaged. Perhaps we may be excused if we fail to see the necessity of publishing this chapter separately in advance. It certainly contains much information from German works, such as Heiden's "Düngerlehre," but the book is written mainly from the chemist's point of view and not from the farmer's. The pamphlet gives one the impression of having been hurriedly prepared, but no doubt its deficiencies will be remedied in the larger book.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Peripatus from St. Vincent.

SOME of the readers of NATURE will doubtless be interested to learn that, while collecting in St. Vincent on behalf of the Committee appointed for the investigation of the fauna and flora of the Lesser Antilles, Mr. H. H. Smith obtained five examples of the genus *Peripatus*.

The importance of the discovery, or rather rediscovery, of this Arthropod in St. Vincent rests upon the fact that the Rev. L. Guilding procured the first recorded examples of the genus in this same island. A description of these, under the name *juliformis*, was published by this naturalist in 1826, in vol. ii. of the *Zoological Journal.* But from that time until now, a period of 66 years, no additional specimens have been brought to light in this locality; and since Guilding's types have been lost sight of, and his description of them is wanting in detail, the identity of *juliformis* has been involved in considerable obscurity. There can, however, be little if any doubt that the examples collected by Mr. H. H. Smith are specifically identical with those that Guilding described. Nevertheless this assumption receives more support from identity of locality than from the agreement that obtains between the description of *juliformis* and the specimens before me. The largest of these measures 43 mm. in length and 6·5 in width; the smallest, on the contrary, is only 13 mm. long. One example has 34 pairs of legs, two of them 33, one 30, and one 29. The colour of the lower surface may be described as fawn; that of the dorsal side varies from fawn to blackish grey.

Those who are familiar with Mr. Smith's qualifications as a collector need hardly be told that the specimens are on the whole in a satisfactory state of preservation. I consequently hope to be able to prepare a detailed description of the species, to be incorporated in the report upon the Myriopoda of the Lesser Antilles, the identification of the species of this group, together with that of the Scorpions, Pedipalpi, and fresh-water Decapoda, having been kindly intrusted to my care by the members of the Exploration Committee. R. I. POCOCK.

Natural History Museum, May 27.

The Line Spectra of the Elements.

I QUITE agree with Prof. Stoney that Fourier's theorem can be applied to motions which approximate to non-periodic motions in any assigned degree, and for any assigned time. And so the co-ordinates of any arbitrary motion may approximately in any assigned degree and for any assigned time be represented by formulas of this kind:—

$$a_0+a_1\sin\left(\frac{m_1t}{j}+\alpha_1\right)+a_2\sin\left(\frac{m_2t}{j}+\alpha_2\right)+\ldots+a_n\sin\left(\frac{m_nt}{j}+\alpha_n\right),$$

where $m_1, m_2, \ldots m_n$ are positive integers, and j must be chosen sufficiently large to suit the length of the assigned time. This is not the point in Prof. Stoney's reasoning to which I object.

What I want to say is this: If the motion is not periodical, the periods of the circular functions, as well as the amplitudes and phases, are not necessarily definite. That is to say, if we choose a larger value of j, to get a closer approximation for a longer time, the values of $a, \frac{m}{j}, \alpha$ do not necessarily approach definite values, but may become totally different.

Take, for instance, the equation—

$$t = 2j\left[\sin\frac{t}{j} - \tfrac{1}{2}\sin\frac{2t}{j} + \tfrac{1}{3}\sin\frac{3t}{j} - \ . \ . \ . \ \right],$$

which holds good for all values of t between $-j$ and $+j$. Prof. Stoney may say that Fourier's theorem can be applied to the function t. So it can, certainly, if an interval is assigned. But the amplitudes and periods of the single terms are not independent of the length of the interval, and do not approach definite values when the interval increases indefinitely.

The time during which the approximation is to hold good need not be indefinitely long. But the time must be long in comparison with the longest of the periods. Motions of the ether that are represented by such functions will be resolved by a diffraction grating into different rays, but others will not. Prof. Stoney has not noticed that a distinct property of the function is wanted in order to get a proper resolution into a sum of circular functions. His reasonings in chapter iv. of his memoir on the cause of double lines, &c. (Transactions of the Royal Dublin Society, 1891), refer to all functions with or without this property, and therefore do not seem to me to be correct. But I admit that my expression in the passage quoted by Prof. Stoney might have been clearer. C. RUNGE.

Maxwell's Law of Distribution of Energy.

IN the current number of the *Philosophical Magazine*, Lord Kelvin describes a dynamical system in which when in stationary motion Maxwell's law of distribution of energy would fail, assuming that law to consist in the ultimate equality of the energy of different parts of the system. He has thus shown the necessity for more accurate language than is commonly employed in the enunciation of that law, and a consideration of his problem may help to determine the limits to which it is subject.

The following statement, whether co-extensive with Maxwell's law or not, will probably be accepted as true as far as it goes—

If there exist a very great number of material systems, the state of each being defined by certain co-ordinates and momenta, and if at a given instant all combinations of the co-ordinates and momenta are represented among them with frequency proportional to $\epsilon^{-h(\chi+T)}$, then that distribution will be permanent—that is, will not be disturbed by the mutual action of the systems, or by any forces in the field of which they are placed, provided all the forces concerned be conservative.

The further question as to how far the solution thus found for the permanent state is unique, has been treated by Boltzmann. He shows that a certain function, which in stationary motion must be positive and constant, necessarily diminishes with the time, so long as any small deviations exist from the above described state. It is obvious that this proposition of Boltzmann's cannot be applicable to all cases of stationary motion. Periodic motions are exceptions, and so is the system described by Lord Kelvin. The question is what assumptions underlie Boltzmann's demonstration. It will be of great advantage if one speaking with Lord Kelvin's authority will assist in defining the limits to which the proposition is subject.

Maxwell, although he may at times have expressed himself incautiously, was aware that the theory was subject to limitations. The statistical, as distinguished from the historical, method was from his point of view of the essence of the theory. A distinction may be drawn between systems, such as Lord Kelvin's, to which the statistical method is inapplicable, and those in which the stationary motion, when attained, is what is called thermal motion—that is, the relative motions are in all directions indifferently, and of that irregular character in which heat is supposed to consist.

It may be that we shall be driven to the conclusion that Maxwell's law has no application except to this class of systems; that it is, in fact, only the limiting state to which a material system approaches as we increase indefinitely the number of its degrees of freedom.

It does, at all events, appear that in cases where the law fails, its failure is due to the introduction of some restrictions on freedom of motion, especially as regards direction. Maxwell pointed out that dæmons—or, shall we say, beings endowed with free will—might by directing the courses of individual molecules cause a system to violate, not only the law of distribution of energy, but even the second law of thermodynamics. What these beings might be supposed to do, that Lord Kelvin in fact does once for all for his system, by prescribing *a priori* the directions of motion and other conditions of the problem to suit his purpose.

The Former Connection of Southern Continents.

WITH reference to the very interesting question treated in Mr. Mellard Reade's letter of your issue of May 26 (p. 77), as to the former connection of southern continents, it may be worth while calling attention to the fact that a great circle, which I may call the Kaffraria Great Circle, connects that coast line with the Falkland Island and the South Georgia Island. It may be presumed that these two islands are the remaining summits of what was once a chain of mountains in connection with the continent of South America. Some of the points through which or near which this great circle passes are as follow—the above-mentioned islands, Port de Sta. Cruz, Patagonia; it traverses the Pacific, runs parallel to the southern branch of the Aleutian Islands, and cuts Kamtchatka somewhat south of Klienchewskaia Volcano, and traversing Asia emerges by the Island of Cutch, so interesting on account of the earthquakes which occurred there. It is of interest to note that South Georgia Island is antipodal to the northern extremity of Saghalian Island.

Stephen's Green, Dublin, May 30.

ON THE RELATIVE DENSITIES OF HYDROGEN AND OXYGEN.[1]

IN a preliminary notice upon this subject (Roy. Soc. Proc., vol. xliii. p. 356, February 1888), I explained the procedure by which I found as the ratio of densities 15·884. The hydrogen was prepared from zinc and sulphuric, or from zinc and hydrochloric, acid, and was liberated upon a platinum plate, the generator being in fact a Smee cell, inclosed in a vessel capable of sustaining a vacuum, and set in action by closing the electric circuit at an external contact. The hydrogen thus prepared was purified by corrosive sublimate and potash, and desiccated by passage through a long tube packed with phosphoric anhydride. The oxygen was from chlorate of potash, or from mixed chlorates of potash and soda.

In a subsequent paper "On the Composition of Water" (Roy. Soc. Proc., vol. xlv. p. 425, February 1889), I attacked the problem by a direct synthesis of water from weighed quantities of the two component gases. The ratio of atomic weights thus obtained was 15·89.

At the time when these researches were commenced, the latest work bearing upon the subject dated from 1845, and the number then accepted was 15·96. There was, however, nothing to show that the true ratio really deviated from the 16 : 1 of Prout's law, and the main object of my work was to ascertain whether or not such deviation existed. About the year 1888, however, a revival of interest in this question manifested itself, especially in the United States, and several results of importance have been published. Thus, Prof. Cooke and Mr. T. W. Richards found a number which, when corrected for an error of weighing that had at first been overlooked, became 15·869.

The substantial agreement of this number with those obtained by myself, seemed at first to settle the question, but almost immediately afterwards there appeared an account of a research by Mr. Keiser, who used a method presenting some excellent features, and whose result was as high as 15·949. The discrepancy has not been fully explained, but subsequent numbers agree more nearly with the lower value. Thus, Noyes obtains 15·896, and Dittmar and Henderson give 15·866.

I had intended further to elaborate and extend my observations on the synthesis of water from weighed quantities of oxygen and hydrogen, but the publication of Prof. E. W. Morley's masterly researches upon the "Volumetric Composition of Water" (*Amer. Journ. Sci.*, March 1891) led me to the conclusion that the best contribution that I could now make to the subject would be by the further determination of the relative densities of the two gases. The combination of this with the number 2·0002,[2] obtained by Morley as the mean of astonishingly concordant individual experiments, would give a better result for the atomic weights than any I could hope to obtain directly.

In the present work two objects have been especially kept in view. The first is simplicity upon the chemical side, and the second the use of materials in such a form that the elimination of impurities goes forward in the normal working of the process. When, as in the former determinations, the hydrogen is made from zinc, any impurity which that material may contain and communicate to the gas cannot be eliminated from the generator; for each experiment brings into play a fresh quantity of zinc, with its accompanying contamination. Moreover, the supply of acid that can be included in one charge of the generator is inadequate, and good results are only obtained as the charge is becoming exhausted. These difficulties are avoided when zinc is discarded. The only material consumed during the experiments is then the water, of which a large quantity can be included from the first. On the other hand, the hydrogen liberated is necessarily contaminated with oxygen, and this must be removed by copper contained in a red-hot tube. In the experiments to be described the generator was charged with potash,[1] and the gases were liberated at platinum electrodes. In the case of a hydrogen filling, the oxygen blew off on one side from a mercury seal, and on the other the hydrogen was conveyed through hot tubes containing copper. The bulk of the aqueous vapour was deposited in a small flask containing strong solution of potash, and the gas then passed over solid potash to a long tube packed with phosphoric anhydride. Of this only a very short length showed signs of being affected at the close of all operations.

---

[1] "On the Relative Densities of Hydrogen and Oxygen. II." Abstract of a paper by Lord Rayleigh, Sec.R.S., read at the Royal Society on February 18, 1892.

[2] It should not be overlooked that this number is difficult to reconcile with views generally held as to the applicability of Avogadro's law to very rare gases. From what we know of the behaviour of oxygen and hydrogen gases under compression, it seems improbable that volumes which are as 2·0002 : 1 under atmospheric conditions would remain as 2 : 1 upon indefinite expansion. According to the formula of Van der Waals, a greater change than this in the ratio of volumes is to be expected.

With respect to impurities, other than oxygen and oxides of hydrogen, which may contaminate the gas, we have the following alternative. Either the impurity is evolved much more rapidly than in proportion to the consumption of water in the generator, or it is not. If the rate of evolution of the impurity, reckoned as a fraction of the quantity originally present, is not much more rapid than the correspondingly reckoned consumption of water, the presence of the impurity will be of little importance. If, on the other hand, as is probable, the rate of evolution is much more rapid than the consumption of water, the impurity is soon eliminated from the residue, and the gas subsequently generated becomes practically pure. A similar argument holds good if the source of the impurity be in the copper, or even in the phosphoric anhydride; and it applies with increased force when at the close of one set of operations the generator is replenished by the mere addition of water. It is, however, here assumed that the apparatus itself is perfectly tight.

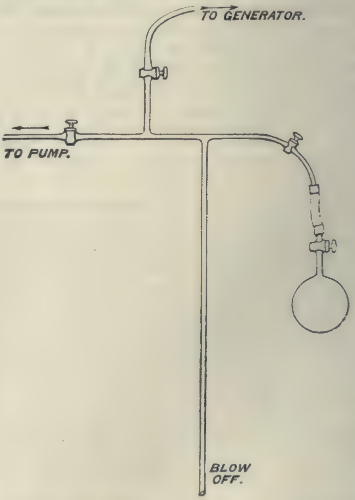
Except for the reversal of the electric current, the action of the apparatus is almost the same whether oxygen or hydrogen is to be collected. In the latter case the copper in the hot tubes is in the reduced, and in the former case in the oxidized, state. For the sake of distinctness we will suppose that the globe is to be filled with hydrogen.

The generator itself is of the U-form, with unusually long branches, and it is supplied from Grove cells with about 3 amperes of electric current. Since on one side the oxygen blows off into the air, the pressure in the generator is always nearly atmospheric. Some trouble has been caused by leakage between the platinum electrodes and the glass. In the later experiments to be here recorded these joints were drowned with mercury. On leaving the generator the hydrogen traverses a red-hot tube of hard glass charged with copper,[2] then a flask containing a strong solution of potash, and afterwards a second similar hot tube. The additional tube was introduced with the idea that the action of the hot copper in promoting the union of the hydrogen with its oxygen contamination might be more complete after removal of the greater part of the oxygen, whether in the combined or in the uncombined state. From this point onward the gas was nearly dry. In the earlier experiments the junctions of the hard furnace tubes with the soft glass of the remainder of the apparatus were effected by fusion. One of these joints remained in use, but the others were replaced by india-rubber connexions *drowned in mercury*. It is believed that no leakage occurred at these joints; but as an additional security a tap was provided between the generator and the furnace, and was kept closed whenever there was no forward current of hydrogen. In this way the liquid in the generator would be protected from any possible infiltration of nitrogen. Any that might find its way into the furnace tubes could easily be removed before the commencement of a filling.

Almost immediately upon leaving the furnace tubes the gas arrives at a tap which for distinctness may be called the regulator. In the generator and in the furnace tubes the pressure must be nearly atmospheric, but in the globe there is (at the commencement) a vacuum. The transition from the one pressure to the other takes place at the regulator, which must be so adjusted that the flow through it is approximately equal to the production of gas. At first the manipulation of the regulator was a source of trouble, and required almost constant attention, but a very simple addition gave the desired control. This was merely a long wooden arm, attached to the plug, which served both as a lever and as an indicator. Underneath the pointed extremity was a small table to which its motions could be referred. During the first two-thirds of a filling very little readjustment was needed, and the apparatus could be left for half an hour with but little fear of displacing too much the liquid in the generator. Towards the close, as the motive force fell off, the tap required to be opened more widely. Sometimes the recovery of level could be more conveniently effected by insertion of resistance into the electric circuit, or by interrupting it altogether for a few minutes. Into details of this kind it is hardly necessary to go further.

From the regulator the gas passed to the desiccating tubes. The first of these was charged with fragments of solid potash, and the second with a long length of phosphoric anhydride. Finally, a tube stuffed with glass wool intercepted any suspended matter that might have been carried forward.

The connection of the globe with the generator, with the Töppler, and with the blow-off, is shown in the accompanying figure. On the morning of a projected filling the vacuous globe would be connected with the free end of the stout-walled india-rubber tube, and secured by winding wire. The generator being cut off, a high vacuum would be made up to the tap of the globe.



---

[1] At the suggestion of Prof. Morley, the solution was freed from carbonate or nearly so, by the use of baryta, of which it contained a slight excess.

[2] The copper must be free from sulphur; otherwise the contamination with sulphuretted hydrogen is somewhat persistent.

After a couple of hours' standing the leakage through the india-rubber and at the joints could be measured. The amount of the leakage found in the first two hours was usually negligible, considered as an addition to a globeful of hydrogen, and the leakage that would occur in the hours following would (in the absence of accidents) be still smaller. If the test were satisfactory, the filling would proceed as follows:—

The electric current through the generator being established, and the furnace being heated, any oxygen that might have percolated into the drying tubes had first to be washed out. In order to do this more effectively, a moderate vacuum (of pressure equal to about 1 inch of mercury) was maintained in the tubes and up to the regulator by the action of the pump. In this way the current of gas is made very rapid, and the half-hour allowed must have been more than sufficient for the purpose. The generator was then temporarily cut off, and a high vacuum produced in the globe connection and in the blow-off tube, which, being out of the main current of gas, might be supposed to harbour impurities. After this the pump would be cut off, the connection with the generator re-established, and, finally, the tap of the globe cautiously opened.

The operation of filling usually occupied from two to three hours. When the gas began to blow off under an excess of pressure represented by about half an inch of mercury, the blow-off cistern was lowered so as to leave the extremity of the tube free. For two minutes the current of gas from the generator was allowed to flow through, after which the generator was cut off, and the globe left in simple communication with the atmosphere, until it was supposed that equilibrium of pressure had been sufficiently established. Doubts have at various times been felt as to the interval required for this purpose. If too little time is allowed, there will remain an excess of pressure in the globe, and the calculated weight of the filling will come out too high. On the other hand, an undue prolongation of the time might lead to a diffusion of air back into the globe. In a special experiment no abnormal weight was detected after half an hour's communication, so that the danger on this side appeared to be small. When the passages through the taps were free from grease, one or two minutes sufficed for the establishment of equilibrium, but there was always a possibility of a partial obstruction. In the results to be presently given, four minutes were allowed after the separation from the generator. It may be remarked that a part of any minute error that may arise from this source will be eliminated in the comparison with oxygen, which was collected under like conditions.

The reading of the barometers and thermometers at the moment when the tap of the globe was turned off took place as described in the former paper. The arrangements for the weighings were also the same.

In the evacuations the process was always continued until, as tested by the gauge of the Töppler after at least a quarter of an hour's standing, the residue could be neglected. Here, again, any minute error would be eliminated in the comparison of the two gases.

In the case of oxygen, the errors due to contamination (even with hydrogen) are very much diminished, and similar errors of weighing tell very much less upon the proportional agreement of the final numbers. A comparison of the actual results with the two kinds of gas does not, however, show so great an advantage on the side of the oxygen as might have been expected. The inference appears to be that the individual results are somewhat largely affected by temperature errors. Two thermometers were, indeed, used (on opposite sides) within the wooden box by which the globe is surrounded, and they could easily be read to within $\frac{1}{20}$° C. But in other respects, the circumstances were unfavourable, in consequence of the presence in the same room of the furnace necessary to heat the copper. An error of ± 0°·1 C. in the temperature leads to a discrepancy of 1 part in 1500 in the final numbers. Some further elaboration of the screening arrangements actually employed would have been an improvement, but inasmuch as the circumstances were precisely the same for the two gases, no systematic error can here arise. The thermometers were, of course, the same in the two cases.

The experiments are grouped in five sets, two for oxygen and three for hydrogen. In each set the work was usually continued until the tap of the globe required re-greasing, or until, owing to a breakage or to some other accident, operations had to be suspended.

The means are as follow:—

HYDROGEN.

1891.	Weight.	Bar. temp., F.	Globe temp., C.	Corrected to 12°.
	gram.	°	°	gram.
July	0·15808	65	18	0·158056
September	0·15797	61	17	0·157950
October	0·15804	53	12	0·158040
Mean		60	16	0·158015

OXYGEN.

1891.	Weight.	Bar. temp., F.	Globe temp., C.	Corrected to 12°.
	grams.	°	°	grams.
June..............	2·51785	68	20	2·51735
November	2·51720	55	13	2·51713
Mean		61½	16½	2·51724

The means here exhibited give the weights of the two gases as they would be found with the globe at 12° C., and the barometers at 60° F. and at 30 inches. The close agreement of the mean temperatures for the two gases shows how little room there is for systematic error dependent upon imperfections in the barometers and thermometers. But the results still require modification before they can be compared with the view of deducing the relative densities of the gases.

In the first place, there is a systematic, though minute, difference in the pressures hitherto considered as corresponding. The terminal of the blow-off tube is 33 inches below the centre of the globe at the time of filling. In the one case this is occupied by hydrogen, and in the other by oxygen. If we treat the latter as the standard, we must regard the hydrogen fillings as taking place under an excess of pressure equal to $\frac{15}{16}$ of the weight of a column of oxygen 33 inches high; and this must be compared with 30 inches of mercury. Hence, if we take the sp. gr. of oxygen under atmospheric conditions at 0·0014, and that of mercury at 13·6, the excess of pressure under which the hydrogen was collected is as a fraction of the whole pressure

$$\frac{33}{30} \cdot \frac{15}{16} \cdot \frac{0·0014}{13·6} = 0·000106;$$

and 0·000106 × 0·158 = 0·000017. This, then, is what we must subtract from the weight of the hydrogen on account of the difference of pressures due to the gas in the blow-off tube. Thus

$$H = 0·157998, \qquad O = 2·51724.$$

But there is still another and a more important correction to be introduced. In my former paper it was shown that when the weighings are conducted in air the true weight of the gas contained in the globe is not given by merely subtracting the weight of the globe when empty from the weight when full. When the globe is empty, its external volume is less than when full, and thus, in order to obtain the true weight, the apparent weight of the gas must be increased by the weight of air whose volume is equal to the change of volume of the globe.

In order to determine the amount of this change of volume, the globe is filled to the neck with recently boiled distilled water, and the effect is observed upon the level in the stem due to a suction of, say, 20 inches of mercury. It is not advisable to carry the exhaustion much further, for fear of approaching too nearly the point at which bubbles of vapour may be formed internally. In the earlier experiments, described in the preliminary note, the upper surface of the liquid was in the stem of the globe itself (below the tap), and the only difficulty lay in the accurate estimation of a change of volume occurring in a wide and somewhat irregular tube. The method employed was to produce, by introduction of a weighed quantity of mercury, a rise of level equal to that caused by the suction.

The advantage of this procedure lay in the avoidance of joints and of the tap itself, but, for the reasons given, the readings were not quite so accurate as might be desired. I wished, therefore, to supplement, if possible, the former determination by one in which the change of volume occurred in a tube narrower and of better shape. With this object in view, the stem of the globe was prolonged by a graduated tubular pipette attached with the aid of india-rubber. The tubes themselves were treated with gutta-percha cement, and brought almost into contact. It had hardly been expected that the joint would prove unyielding under the applied suction, but it was considered that the amount of the yielding could be estimated and allowed for by operations conducted *with tap closed*. The event, however, proved that the yielding at the joint was scarcely, if at all, perceptible.

The pipette, of bore such that 16 cm. corresponded to 1 c.c., was graduated to 0·01, and was read by estimation to 0·001 c.c. In order the better to eliminate the changes due to temperature, readings under atmospheric pressure, and under a suction of 20 inches of mercury, were alternated. On January 28, 1892, a first set gave 0·648 − 0·300 = 0·348; a second gave 0·6645 − 0·316 = 0·3485; and a third gave 0·675 − 0·326 = 0·349. Similar operations with tap closed[1] gave no visible movement.

The result of the day's experiments was thus 0·3485 for 20 inches, or 0·523 for 30 inches, suction. Similar experiments on January 28, at a different part of the graduation, gave 0·526. On this day the yielding with tap closed was just visible, and was estimated at 0·001. As a mean result, we may adopt 0·524 c.c. The graduation of the pipette was subsequently verified by weighing a thread of mercury that occupied a measured length.

A part of the above-measured volume is due to the expansion of the water when the pressure is relieved. We may take this at 0·000047 of the volume per atmosphere. The volume itself may be derived with sufficient accuracy for the present purpose from the weight of its oxygen contents. It is 2·517/0·00137, or 1837 c.c. The expansion of the water per atmosphere is thus 0·000047 × 1837, or 0·087 c.c. This is to be subtracted from 0·524, and leaves 0·437 c.c. This number applies strictly to the volume inclosed within the glass, but the change in the external volume of the globe will be almost the same.

The correction now under consideration is thus the weight of 0·437 c.c. of air at the average temperature of the balance room. The density of this air may be estimated at 0·00122; so that the weight of 0·437 c.c. is 0·000533 gram. This is the quantity which must be added to the apparent weights of the gases. The former estimate was 0·00056 gram. The finally corrected weights are thus—

$$H = 0·158531, \qquad O = 2·51777;$$

and for the ratio of densities we have

$$15·882.$$

This corresponds to a mean atmospheric condition of pressure and temperature.

If we combine the above ratio of densities with Prof. Morley's ratio of volumes, viz. 2·0002 : 1, we get, as the ratio of atomic weights, 15·880.

If we refer to the table, we see that the agreement of the first and third series of hydrogen weighings is very good, but that the mean from the second series is decidedly lighter. This may have been in part fortuitous, but it is scarcely probable that it was so altogether. Under the circumstances we can hardly reckon the accuracy of the final results as closer than $\frac{1}{3000}$.

The accompanying table of results, found by various experimenters, may be useful for comparison:—

Name.	Date.	Atomic weights.	Densities.
Dumas	1842	15·96	—
Regnault	1845	—	15·96
Rayleigh	1888	—	15·884
Cooke and Richards ...	1888	15·869	—
Keiser	1888	15·949	—
Rayleigh	1889	15·89	—
Noyes	1890	15·896	—
Dittmar	1890	15·866	—
Morley	1891	15·879	—
Leduc	1891	—	15·905
Rayleigh	1892	—	15·882

[1] For greater security the tap was turned while the interior was under suction.

THE ORIGIN OF THE YEAR.[1]

II.

Difficulties.

There no doubt was a time when the Egyptian astronomer-priests imagined that, by the introduction of the 365-days year, beginning at the solstice or the nearly contemporaneous Nile flood (there is an interval of three days between them in the present Coptic calendar[2]), and by marking the commencement, in addition, by the heliacal rising of one of the host of heaven, they had achieved finality. But alas! the dream must soon have vanished.

Even with this period of 365 days, the true length of the year had not been reached; and soon, whether by observations of the beginning of the inundation, or by observations of the solstice in some of the solar temples which, beyond all doubt, were then in existence, it was found that there was a difference of a day every four years between the beginning of the natural and of the newly-established year, arising, of course, from the fact that the true year is 365 days *and a quarter of a day* (roughly) in length.

The true year and this established year of 365 days, then, behaved to each other as follows. Let us take a year when the solstice, representing the beginning of the

---

[1] Continued from vol. xlv. p. 490.

[2] The calendar in question (given both by Brugsch and De Rougé) is, doubtless, a survival from old Egyptian times. It is good for the neighbourhood of Cairo, and the relation of the important days of the inundation to the solstice, in that part of the river, is as follows:—

Night of the drop	11 Payni	
	15 ,, ...	Summer solstice.
Beginning of the inundation ...	18 ,, ...	3 days after.
Assembly at the Nilometer ...	25 ,, ...	10 ,,
Proclamation of the inundation ...	26 ,, ...	11 ,,
Marriage of the Nile	18 Mesori ...	63 ,,
The Nile ceases to rise...	16 Thoth ...	96 ,,
Opening of the dams	17 ,, ...	97 ,,
End of the greater inundation ...	7 Phaophi ...	117 ,,

true year, occurred on the 1st Thoth of the established year. We should have, in the subsequent years, the state of things described in the diagram. The solstice would year by year occur *later* in relation to the 1st of Thoth. The 1st of Thoth would occur *earlier*, in relation to the solstice; so that in relation to the established year the solstice would sweep forwards among the days; in relation to the true year the 1st of Thoth would sweep backwards.

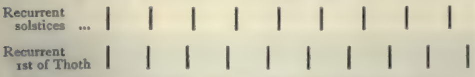

FIG. 2.—Showing the relation between the recurrences of the solstices and the 1st of Thoth.

Let us call the true natural year a *fixed* year: it is obvious that, the months of the 365-day year would be perpetually varying their place in relation to those of the fixed year. Let us, therefore, call the 365-day year a *vague* year.

Now if the fixed year were exactly 365¼ days long, it is quite clear that, still to consider the above diagram, the 1st of Thoth would again coincide with the solstice in 1460 years, since in 4 years the solstice would fall on the 2nd of Thoth, in 8 years on the 3rd of Thoth, and so on (365 × 4 = 1460).

But the fixed year is not 365¼ days long *exactly*. In the time of Hipparchus 365·25 did not really represent the true length of the solar year; instead of 365·25 we must write 365·242392—that is to say, the real length of the year is a little *less* than 365¼ days.

Now the length of the year being a little *less*, of course we should only get a second coincidence of the 1st of Thoth vague with the solstice in a *longer* period than the 1460-years cycle; and, as a matter of fact, 1506 years are required to fit the months into the years with this slightly shortened length of the year. In the case of the solstice and the vague year, then, we have a cycle of 1506 years.

The variations between the fixed and vague years were known perhaps for many centuries to the priests alone. They would not allow the established year of 365 days, since called the *vague* year, to be altered; and so strongly did they feel on this point that, as already stated, every king had to swear when he was crowned that he would not alter the year. We can surmise why this was. It gave great power to the priests; they alone could tell on what particular day of what particular month the Nile would rise in each year, because they alone knew in what part of the cycle they were; and in order to get that knowledge they had simply to continue going every year into their Holy of Holies one day in the year as the priests did afterwards in Jerusalem, and watch the little patch of bright sunlight coming into the sanctuary. That would tell them exactly the relation of the true solar solstice to their year; and the exact date of the inundation of the Nile could be predicted by those who could determine observationally the solstice, but by no others.

But now suppose that instead of the solstice we take the heliacal rising of Sirius, and compare the successive risings at the solstice with the 1st of Thoth.

But why, it will be asked, should there be any difference in the length of the cycles depending upon successive coincidences of the 1st of Thoth with the solstice and the heliacal rising of Sirius? The reason is that stars change their places, and the star to which they trusted to warn them of the beginning of a new year was, like all stars, subject to the effects brought about by the precession of the equinoxes. Not for long could it continue to rise heliacally either at the solstice or the Nile flood.

Among the most important contributors to the astronomical side of this subject are M. Biot and Prof. Oppolzer. It is of the highest importance to bring together the fundamental points which have been made out by their calculations. We have determinate references to the heliacal rising of Sirius, to the 1st of Thoth, to the solstice, and to the rising of the Nile in connection with the Egyptian year; but, so far as I have been able to make out, we find nowhere at present any sharp reference to the importance of their correlation with the times of the *tropical* year at which these various phenomena took place. The question has been complicated by the use by chronologists of the Julian year in such calculations; so the Julian year and the use made of it by chronologists have to be borne in mind. Unfortunately, many side issues have in this way been raised.

The heliacal rising of Sirius, of course—if in those days a true *tropical* year was being dealt with—would have given us a more or less constant variation in the time of the rising over a long period, *on account of its precessional movement;* but M. Biot and others before him have pointed out that the variation in the time of the year at which the heliacal rising took place, produced by that movement, was almost exactly equal to the error of the *Julian* year as compared with the true tropical or Gregorian one. Biot showed by his calculations, using the solar tables extant before those of Leverrier, that from 3200 B.C. to 200 B.C. in the Julian year of the chronologists, Sirius had constantly, in each year, risen heliacally on July 20 Julian = June 20 Gregorian. Oppolzer, more recently, using Leverrier's tables, has made a very slight correction to this, which, however, is practically immaterial for the purposes of a general statement. He shows that in the latitude of Memphis, in 1600 B.C., the heliacal rising took place on July 18·6, while in the year 0 it took place on July 19·7, both Julian dates.

The variation from the true tropical year brought about by the precessional movement of Sirius or any other star, however, can be watched by noting its heliacal rising in relation to any physical phenomenon which marks the true length of the tropical year. Such a phenomenon we have in the rising of the Nile, which, during the whole course of historical time, has been found to rise and fall with absolute constancy in each year, the initial rise of the waters, some little way above Memphis, taking place very nearly at the summer solstice.

Again, M. Biot has made a series of calculations from which we learn that the heliacal rising of Sirius AT THE SOLSTICE occurred on July 20 (Julian) in the year 3285 B.C., and that in the year 275 B.C. the *solstice* occurred on June 27 (Julian), while the heliacal *rising of Sirius* took place, as before, on July 20 (Julian), so that in Ptolemaic times, at Memphis, there was a difference of time of about 24 days between the heliacal rising of Sirius and the solstice, and therefore the beginning of the Nile flood in that part of the river. This, among other things, is shown in Fig. 3.

We learn from the work of Biot and Oppolzer then that the precessional movement of the star caused successive heliacal risings of Sirius at the solstice to be separated by almost exactly 365¼ days—that is, by a greater period than the length of the true year. So that, in relation to this star, two successive heliacal risings at the 1st of Thoth vague are represented by a period of (365¼ × 4 =) 1461 years, while in the case of the solstices we want 1506.

Now in books on Egyptology the period of 1461 years is termed the Sothic period, and truly so, as it very nearly correctly measures the period elapsing between two heliacal risings at the solstice (or the beginning of the Nile flood) on the 1st of Thoth in the *vague* year.

But it is merely the result of *chance* that 365¼ × 4 represents it. It has been stated that this period had not any ancient existence, but was calculated back in later times. This seems to me very improbable. I look upon it rather as a true result of observation, the more so as the period was shortened *in later times*, as Oppolzer has shown.

It will be seen that our investigations land us in several astronomical questions of the greatest interest, and that the study is one in which modern computations, with the great accuracy which the work of Leverrier and others give to them, can come to the rescue, and eke out the scantiness of the ancient records.

To consider the subject further, we must pass from the mere question of the year to that of chronology generally, but in doing so I shall limit myself to the more purely astronomical part. To go over the already vast literature is far from my intention, nor is it necessary to attempt to settle all the differences of opinion which exist, and which are so ably referred to by Krall in his masterly analysis, to which I own myself deeply indebted. The tremendously involved state of the problem may be gathered from the fact that the authorities are not yet decided whether many of the dates really belong to a fixed or a vague year!

Let us, rather, put ourselves in the place of the old Egyptians, and inquire how, out of the materials they had at hand, a calendar could be constructed in the simplest way.

To make what follows clearer, it will be well to construct another diagram somewhat like the former one.

Let us map out the 1460 years which elapsed between two successive coincidences between the 1st of Thoth in the vague year and the heliacal rising of Sirius at the solstice, so that we can see at a glance the actual num-

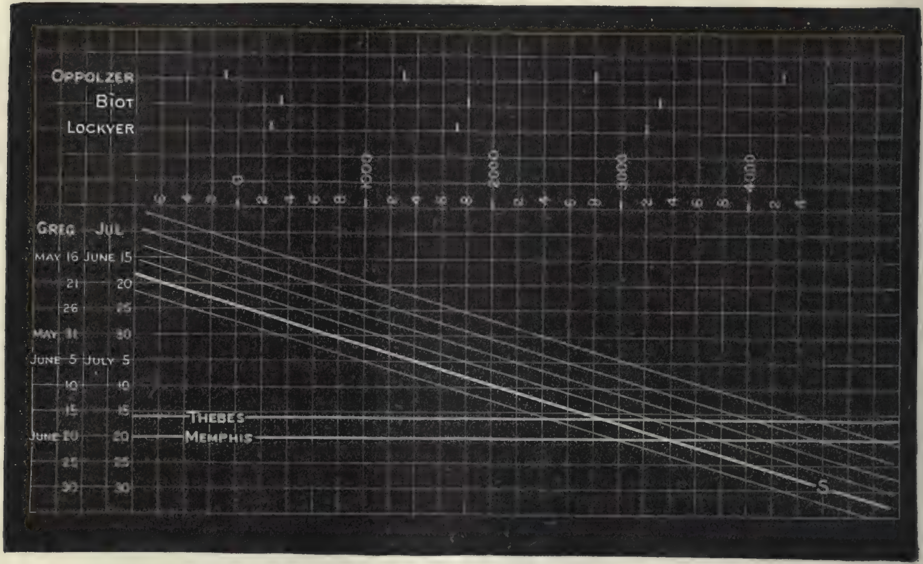

Fig. 3.—The conditions of the heliacal rising of Sirius from 4000 B.C. to 600 A.D. The diagram shows (1) by white horizontal lines, the Gregorian and Julian dates for the rising at Thebes and at Memphis. (2) By the full diagonal line the *Julian* date of the solstice or beginning of the inundation in each century, at a point of the river near Memphis. The fainter lines show the Julian dates for other places where the time of the beginning of the flood differs by three days from the Memphis dates. The interval between each line represents a difference of three days in the arrival of the flood (3) The interval in days between the heliacal rising and the inundation at different periods and at different points on the river. This can be determined for each century by noticing the interval between the proper diagonal line and that indicating the heliacal rising. (4) By dots at the top of the diagram the commencement of the Sothic period as determined by Oppolzer, Biot, and the author.

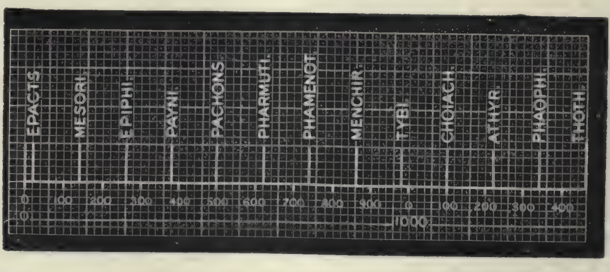

Fig. 4.—The distribution of the 1st of Thoth (representing the rising of Sirius) among the Egyptian months in the 1460-year Sothic cycle.

ber of years from any start point (= 0) at which the 1st of Thoth in the vague year occurred successively further and further from the heliacal rising, until at length, after a period of 1460 years, it coincided again.

As the Sirius-year is longer than the vague one, the first vague year will be completed before the first Sirius-year, hence the second vague year will commence just before the end of the fixed year, and that is the reason that I have reversed the order of months in the diagram (Fig. 4).

Now it is clear that, if the Egyptians really worked in this fashion, any special day in the vague year given as the date of the heliacal rising of Sirius would enable us to determine the number of years which had elapsed from the beginning of the cycle. This will help us to determine whether or not they acted on this principle, or used one widely different. In such an investigation as this, however, we are terribly hampered by the uncertainty of Egyptian dates; while, as I have said before, there is great divergence of opinion among Egyptologists as to whether, from very early times, there was not a true fixed year.

But let us suppose that the vague year was in use, and that the rising of Sirius started the year; then, if we can get any accepted date to work with, and use the diagram to see how many years had elapsed between that date and the start-point of the cycle, we shall see if there be any cyclical relation, and if we find it, it will be evidence, so far as it goes, of the existence of a vague year.

Now it so happens that there are three references, with dates given, to the rising of Sirius in widely different times; and, curiously enough, the month references are nearly the same. I begin with the most recent, as in this case the date can be fixed with the greater certainty. It is an inscription at Philæ, described by Brugsch (p. 87), who states that, when it was written, the 1st of Thoth = 28th of Epiphi. That is, according to the view we are considering, the heliacal rising of Sirius occurred on the 28th of Epiphi in the vague year. He fixes the date of the inscription between 127 and 117 B.C. Let us take it as 122. Next, referring to our diagram to find how many years had elapsed since the beginning of the cycle, we have—

Days.
5 Epacts.
30 Mesori.
2 Epiphi.
—
$37 \times 4 = 148$ years elapsed.

The cycle, then, began in $(148 + 122 =)$ 270 B.C.

We next find a much more ancient inscription recording the rising of Sirius on the 28th of Epiphi. Obviously, if the Sothic cycle had anything to do with the matter, this must have happened 1458 years earlier, *i.e.* about $(1458 + 122 =)$ 1580 B.C. Under which king? Thotmes III., who reigned, according to Lepsius, 1603–1565 B.C.; according to Brugsch, 1625–1577. Now, the inscription in question is stated to have been inscribed by Thotmes III., and, it may be added, on the temple (now destroyed) at Elephantiné.

There is yet another inscription, also known to be of a still earlier period, referring to the rising of Sirius on the 27th of Epiphi. We may neglect the difference of one day; and again, if the use of the Sothic cycle were the origin of the identity of dates, we have this time, according to Oppolzer, a period of 1460 years to add: this gives us $(1584 + 1460 =)$ 3044 B.C. Again under which king? Here we are face to face with one of the difficulties of these inquiries. It may be stated, however, that the inscription is ascribed to Pepi, and that, according to various authorities, he reigned some time between 3000 and 3700 B.C.

We come, then, to this: that one of the oldest dated inscriptions known seems to belong to a system which continued in use at Philæ up to about 100 B.C., and it was essentially a system of a vague year.

Now, assuming that the approximate date of the earliest inscription is 3044 B.C., and that it represented the heliacal rising of Sirius on the 27th of Epiphi; the year 3044 must have been the $[(5 + 30 + 3) \times 4 =]$ 152nd after the beginning of the cycle. The cycle, then, must have commenced $(3044 + 152 =)$ 3196 B.C.

According to Biot's calculation, the first heliacal rising of Sirius at the solstice took place in the year 3285 B.C.,

If we assume that the real date of Pepi, who, it is stated, reigned 100 years, included the year 3044 B.C., it may be that the inscriptions to which I have directed attention give us three Sothic cycles beginning—

$122 + 148 = 270$ B.C.
$1580 + 148 = 1728$ B.C.
$3044 + 148 = 3192$ B.C.

J. NORMAN LOCKYER.

(*To be continued.*)

NOTES.

THE list of those on whom honorary degrees are to be conferred at Cambridge on the occasion of the installation of the Duke of Devonshire as Chancellor shows that culture, and especially scientific culture, goes for very little among the classes of distinction recognized by the University. Eminence in the political world and in society seems to be the claim chiefly recognized.

SCIENCE was well represented at the annual dinner of the Incorporated Society of Authors on Tuesday. The chair was occupied by Prof. Michael Foster, and Sir Archibald Geikie was one of those who responded to the toast of "Literature."

DR. A. F. BATALIN has been appointed Director of the Imperial Botanic Garden at St. Petersburg, in succession to the late Dr. E. Regel.

THE ninety-seventh meeting of the Yorkshire Naturalists' Union will be held on Whit Monday, June 6. Some interesting notes on the physical geography and geology, botany, entomology, conchology, and vertebrate zoology of the district have been issued for the benefit of those who intend to be present. We are glad to see that members are expected to "do all in their power to discourage the uprooting of ferns and rare plants, or the too free collection of rarities of any kind."

THE Botanical Society of France has held its annual meeting at Algiers, commencing April 16, under the presidency of the Algerian botanist, M. Battandier. In addition to the reading of papers, excursions were made to Biskra, and other spots on the border of the Sahara.

WE have received the programme of the ninth International Congress of Orientalists. It is to be held in London from September 5 to 12, Prof. Max Müller acting as President. The Duke of Connaught has accepted the office of Honorary President. The following are the Vice-Presidents: the Marquis of Ripon, Lord Northbrook, Lord Reay, Major-Gen. Sir Henry Rawlinson, the Rt. Hon. Sir M. E. Grant Duff, Sir John Lubbock, Sir William Muir, Sir William W. Hunter, Sir George Birdwood, Sir William Markby, Sir Edwin Arnold, the Provost of Oriel College, Oxford, the Master of Balliol College, Oxford, the Master of Christ's College, Cambridge, H. S. King, and M. M. Bhownuggree. The Treasurer is Mr. E. Delmar Morgan. The Honorary Secretaries are: the Rev. C. D. Ginsburg, D.D., Prof. T. W. Rhys Davids, the Rev. E. W. Bullinger, D.D., Prof. A. A. Macdonell, M. M. Bhownuggree, the Raja Peari Mohan Mukharji (for Bengal), Prof. Peterson (for Bombay). Many eminent foreign scholars and members of former Congresses have signified their adhesion, and several important Societies have undertaken to send delegates. The sections into which the work of the Congress has been provisionally divided, are the following (the name of the President being in each case given first, that of the Secretary second):—I. Aryan, Prof. Cowell, Prof. A. A. Macdonell; II. Semitic (*a*) Assyrian and Babylonian, Prof. A. H. Sayce, T. G. Pinches, (*b*) General, Prof. Robertson Smith, A. A. Bevan; III. China and the Far East, Sir Thomas Wade, (for China) Prof. Douglas, (for Japan) Prof. B. H. Chamberlain; IV. Egypt and Africa, Prof. Le Page Renouf, E. Budge; V. Australasia and Oceania, Sir Arthur Gordon, Rev. R. H. Codrington, D.D.; VI. Anthropological and Mythological, Dr. E. B. Tylor; VII. Indian, Lord Reay, Prof. T. W. Rhys Davids; VIII. Geographical, Sir M. E. Grant Duff, Halford J. Mackinder; IX. Archaic Greece and the East, the Rt. Hon. W. E. Gladstone.

THE Committee of the two International Congresses of Prehistoric Archæology and Zoology, which will be held at Moscow this summer in connection with the Geographical and Anthropological Exhibition, has announced, in accordance with a decision of the Russian Railway Department, that all members of the Congresses and exhibitors at the Exhibition may obtain tickets with a 50 per cent. reduction for travelling to Moscow and back. Exhibits may be sent and will be returned on the same terms. As there are at Moscou two different Societies, the Société des Naturalistes de Moscou and the Society of Friends of Natural Science (*Obschestvo Lubitelei Estestvoznaniya*), it may be worth while to note that it is the latter which is organizing the Exhibition and the two Congresses, and to which all applications for the Exhibition must be made.

IT is stated that the Secretary of State for the Colonies has appointed Miss Doberck, formerly Government Meteorological Observer in Sligo, to be Assistant Meteorologist in Hong Kong. Miss Doberck's father has for some years past been the head of the Meteorological Observatory in Hong Kong.

LIEUTENANT-COLONEL HOLDICH, of the Survey of India, will, it is said, personally superintend the mapping out of Captain Bower's journey across Tibet. The work will be done in the Survey drawing offices at Simla, where Captain Bower is at present engaged in preparing the report of his journey.

IT is bad news for farmers that the diamond-back moth has made its appearance in Yorkshire and Northumberland. Specimens from both counties have been identified by Miss Ormerod.

THE weather during the past week has been noteworthy for the occurrence of thunderstorms, copious rainfall at nearly all places, and excessive temperatures at most of the English stations. In London a severe thunderstorm was experienced on Thursday morning, May 26 (succeeding one that occurred the previous evening), with a heavy downpour of rain varying from 0·7 inch to 1·0 inch in different parts of the metropolis. At 8h. a.m. on Saturday the thermometer registered 76° in London, being the highest recorded at that hour this year. The type of wind has been cyclonic, with light or moderate south-westerly breezes generally. The Meteorological Office report for the week ending May 28, shows that the rainfall was equal to the normal value in the south and east of England, and exceeded it in all other districts; while in the northern parts, in Ireland and in Scotland, the fall was about three times as much as the mean. On Sunday the temperature was considerably lower, but since then it has again become abnormally high, the maxima in the shade registering 75° and upwards in places over the southern parts of the kingdom, 83° being registered in London on Tuesday; and thunder-showers occurred in various places on that day.

THE detailed despatches brought to Marseilles from Port Louis by the mail steamer *Australien* confirm all that was stated in the telegrams relating to the hurricane which devastated Mauritius on April 29. A Reuter's telegram from Marseilles, giving a summary of the despatches, says that the total number of lives lost amounted to 1200, while the list of persons injured exceeded 4000. Strong magnetic disturbances were noticed on April 25, and continued with increasing intensity on the three following days. Several well-defined groups of sun-spots were also noticed at the same time. On the afternoon of the 28th, the eve of the hurricane, there was a vivid display of lightning and a good deal of thunder, while the air grew peculiarly heavy. On the following morning the tempest broke over the island in all its fury, the velocity of the wind at times reaching 112 miles an hour. The sea rose 9 feet above its usual level, a thing unknown since the terrible cyclone of 1818, when the water rose nearly four metres. In Port Louis itself houses fell to the ground in nearly every street. In the Tringlar quarter not a single house was left standing. In fact, there is scarcely a house in the entire colony which does not show some signs of the fury of the storm. Half the sugar crop has been destroyed. An immense number of persons were overwhelmed and killed by the ruins of the falling houses, or were stricken down in the streets, as they fled, by the falling stones and wreckage.

A VERY destructive cyclone passed over various towns in Kansas, on May 27. The storm gave no signs of its approach. Travelling in a north-easterly direction, it struck Wellington (a town containing a population of 10,000) at nine o'clock in the evening, when most people were indoors. Within a few seconds the central parts of the town coming within its track were devastated from end to end. Wellington Avenue, the principal business street, is lined on both sides with ruins, whole blocks of buildings having been shaken and overthrown as violently as if the place had been rocked by an earthquake. Numbers of victims were buried in the ruins, and of those who momentarily survived many were found struggling for their lives in order to escape from the flames which broke out in all directions in consequence of the sudden escape of gas. The towns of Harper and Argona were also visited by the cyclone. In the former town seven people were killed in the wreck of the buildings, and five at the latter. It is estimated that between twenty and thirty people lost their lives in the cyclone; while seventy others have been more or less injured.

ON Tuesday, May 3, a fall of hail mixed with foreign particles was observed in Stockholm, and appears to have extended as far as Christiania. The fall of dust lasted from 1 to 8 p.m., and was abundant enough to allow of considerable quantities being collected. At a meeting of the Geologiska Förening in Stockholm, remarks were made by Baron Nordenskiöld, and Messrs. N. Holst, E. Svedmark, and Törnebohm, from which it appears that the dust contained glassy, isotropic, and various anisotropic particles, hornblende, magnetite, minute scales of mica, metallic iron, and some diatoms.

THE Tiflis *Kavkaz* gives the following description of a meteor of great brilliancy which was observed at Tiflis, on May 10. It appeared at 11 p.m. in the west part of the sky, was of a round shape, and very brilliant. Three seconds after its appearance a part of it separated, moving towards the Mtatsminda Mountain, and disappeared below the horizon, after lighting the slopes of the mountain, the central meteor continuing to move, but having lost for a few seconds its great brilliancy, which, however, soon reappeared. In about 30 seconds after the first appearance of the meteor, a second small part separated from it, increasing in size as it approached the earth. This also disappeared in the west, behind the same mountain, after having brilliantly lighted for two or three seconds its slopes and gorges. After that, the meteor took first a milky coloration, but soon became bright again, and of phosphoric aspect. A third part separated from it, but it was much smaller and not so brilliant as the two former. Finally the meteor disappeared behind the clouds—a white, lighted blot being seen through them—and gradually faded away. The phenomenon lasted altogether about three minutes.

WE learn from the *Pioneer Mail* that a smart shock of earthquake was felt at Madras on May 6, about ten minutes to ten o'clock. The sound heard was at first like distant thunder, and afterwards like a railway train, running close by. The shock was distinctly felt. The weather was cloudy and the atmosphere still at the time.

THE *Annuaire Géologique universel*, founded by Dr. Dagincourt in 1885, and continued under the editorship of Dr. L. Carez for geology, and of M. H. Douvillé for palæontology, has now reached its seventh volume. Each year the work has increased in value, and it now affords an admirable *résumé* of geological literature. Hitherto each volume has been issued in a complete form, but the latest has appeared in four parts. By the arrangement adopted there is some repetition, but this enables information required to be readily obtained. There is first a fairly complete list of papers and other publications, then a systematic account of the various main chronological divisions of formations; this is followed by a description of separate districts; and finally we have a summary of palæontological work. The stratigraphical notes are not always complete in each volume, sometimes two years are grouped in one yearly issue; for instance, this volume contains no account of the Triassic and Tertiary rocks, whilst the Cretaceous works of 1890–91 are here included. The volume contains lists of geologists in France, Belgium, and the British Isles; next year we are promised lists for other European countries. The editors are assisted by a large staff of workers in various countries.

M. E. RIGAUX, of Boulogne-sur-Mer, who has devoted many years to the study of the geology of the Bas Boulonnais, has published an excellent account of this region in the *Mémoires de la Soc. Académ. de Boulogne* (vol. xiv., 108 pp.). The district is of especial interest to English geologists because of the fine development there of the Devonian and Carboniferous rocks, and of the Jurassic series from the Great Oolite upwards. The coal, formerly supposed to lie within the Carboniferous Limestone series, is now known to be true coal measures, over which the older rocks have been thrust. The paper gives an account of several important deep borings, in some of which Silurian rocks have been reached beneath the Jurassic series. Thirteen new species of fossils are described.

DURING the past season, Dr. Sheldon Jackson, the Government Agent of Education in Alaska, introduced into Alaska from Siberia sixteen reindeer. Next year he proposes to establish a herd of reindeer in the neighbourhood of Fort Clarence, and he expects to begin with 100 animals. The *Scientific American*, which records these facts, is of opinion that from an economical point of view the experiment is of the highest interest, because the reindeer is useful as a draught animal for sledges, as well as for its milk, its meat, and its skin. As it flourishes in Siberia, there seems to be no reason why it should not also flourish in Alaska, where the conditions of climate and vegetation are very similar to those of Siberia.

THE editors of the *Entomological Monthly Magazine* note that at the sale of the late Mr. Arthur Naish, of Bristol, at Stevens's Rooms on May 16, some of the extinct (or nearly extinct) species of British Lepidoptera fetched high prices. Seven examples of *Lycæna dispar* (the long extinct British form of *L. Hippothoë*) realized £16 8*s*., or an average of nearly £2 7*s*. each. A lot containing four *Polyommatus Acis* (perhaps extinct) was sold for 18*s*. Eight *Lælia cænosa* (apparently recently extinct) were sold for £3 17*s*. 6*d*. Two *Cleora viduaria* (not found very recently) were knocked down for a guinea. Seven *Noctua subrosea* (long extinct as British, and the continental form of which, *subcærulea*, is very different in appearance) obtained £6 12*s*., one very fine example realizing £2 10*s*.

MR. C. W. DALE, writing from Glanvilles Wootton, records, in the June number of the *Entomologist's Monthly Magazine*, that the effect of the weather upon insect life in Dorsetshire during April was remarkable. Butterflies were unusually plentiful, moths unusually scarce. The conclusion he draws is that easterly winds, with frosts at night, are injurious to moth life, but do not affect butterfly life, so long as there is plenty of blue sky and sunshine. These were the general meteorological conditions in Dorsetshire during April.

MESSRS. LONGMANS, GREEN, AND CO. have issued a new and revised edition (the third) of Mr. W. A. Shenstone's "Practical Introduction to Chemistry." It contains the practical introductory course of work in use at Clifton College. In this edition the author has made several changes which have been suggested by his own experience and that of various friends.

THE forty-fourth part of Cassell's "New Popular Educator" has been published. It includes two coloured maps, one of Asia Minor, the other of Palestine.

CYANIDE of arsenic, $As(CN)_3$, has been prepared by M. Guenez, and is described by him in the current number of the *Comptes Rendus*. It has been obtained by the action of finely divided elementary arsenic upon iodide of cyanogen, CNI, a substance which is usually obtained crystallized in delicate, transparent needles, frequently attaining the length of several inches. About thirty grams of perfectly dry cyanogen iodide were placed in a strong Wurtz flask, together with seven grams of powdered arsenic and sixty to seventy cubic centimetres of carbon bisulphide previously dried over phosphoric anhydride. The air contained in the flask was then displaced by dry carbon dioxide and the flask sealed. The reaction was found to commence in the cold, crystals of tri-iodide of arsenic soon making their appearance. But, in order to complete the conversion of the iodide of cyanogen into arsenic cyanide, it was found necessary to heat the flask for about twenty-four hours over a water-bath. The heating is best carried out in successive periods of seven or eight hours, allowing the flask to cool after each period and subjecting the contents to brisk agitation. Under these circumstances a quantitative yield of arsenic cyanide was obtained, in accordance with the following equation:—

$$2As + 3CNI = AsI_3 + As(CN)_3.$$

In order to isolate the cyanide, advantage was taken of its insolubility in carbon bisulphide, arsenic iodide being readily soluble. The product of the reaction was therefore placed in a continuous extracting apparatus, in which it was thoroughly exhausted with pure carbon bisulphide. The residual cyanide was subsequently dried in a current of carbon dioxide, and preserved in sealed tubes previously filled with the same indifferent gas.

CYANIDE of arsenic obtained in the manner above indicated is a slightly yellow substance consisting of small crystals, which under the microscope are observed to be well formed, and to possess a deep yellow colour by transmitted light. The crystals are extremely deliquescent, being instantly decomposed by water with production of arsenious oxide and prussic acid:

$$2As(CN)_3 + 3H_2O = As_2O_3 + 6HCN.$$

When heated, arsenic cyanide evolves about a third of its cyanogen in the form of gaseous di-cyanogen, the residue consisting of a mixture of free arsenic and paracyanogen. When brought in contact with concentrated sulphuric acid and slightly warmed, mutual decomposition occurs, with liberation of sulphur dioxide and carbon monoxide, the nitrogen remaining in the form of ammonium sulphate. Iodine reacts with arsenic cyanide in an energetic manner, even in the cold, forming iodides of arsenic and cyanogen without the volatilization of any iodine. With potassium chlorate, arsenic cyanide forms a mixture which detonates with considerable violence when struck.

The additions to the Zoological Society's Gardens during the past week include two Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Master Logan; two North African Jackals (*Canis anthus*), four —— Gerbilles (*Gerbillus* sp. inc.), an Egyptian Jerboa (*Dipus ægyptius*), six Leith's Tortoises (*Testudo leithii*), five Common Skinks (*Scincus officinalis*), an Egyptian Eryx (*Eryx jaculus*), a Schneider's Skink (*Eumeces schneideri*), two Crowned Snakes (*Zamenis diadema*), a Hissing Sand-Snake (*Psammophis sibilans*) from Egypt, presented by Dr. J. Anderson, F.R.S., F.Z.S.; a Cinerous Vulture (*Vultur monachus*) from Aden, presented by Mr. W. H. Still; a Common Peafowl (*Pavo cristatus* ♂) from India, presented by Colonel Bagot-Chester; two African Love-Birds (*Agapornis pullaria*) from West Africa, presented by Lady McKenna; a Chinese Goose (*Anser cygnoides* ♂) from China, presented by Miss Hill; two Common Vipers (*Vipera berus*), four Common Snakes (*Tropidonotus natrix*), a Slowworm (*Anguis fragilis*), British, presented by Mr. C. Browne; a Mocassin Snake (*Tropidonotus fasciatus*) from North America, presented by Master Denny Stradling; two Purple-capped Lories (*Lorius domicella*) from Moluccas, two Scaly-breasted Lorikeets (*Trichoglossus chlorolepidotus*) from Timor, deposited; four Common Sheldrakes (*Tadorna vulpanser*, 2 ♂, 2 ♀), four Ringed Doves (*Columba palumbarius*, 2 ♂, 2 ♀), European, purchased; two Black-eared Marmosets (*Hapale penicillata*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Winnecke's Periodic Comet, 1892.—The following ephemeris for this comet has been extracted from *Astronomische Nachrichten*, No. 3083. The comet itself is becoming decidedly brighter, and will be found just between the Great Bear and Leo Minor.

Saturn's Rings.—At the present time the earth may be said to be very nearly in the plane of Saturn's Rings, thus affording observers an opportunity of examining the ring from the sectional point of view. M. Bigourdan communicates to the *Comptes rendus* (No. 21) the results of a study he has just made, with reference to some peculiarities he has found to exist. The preceding arm of the ring, he says, presented nothing very abnormal, but it appeared to thin rather than thicken whilst approaching the planet. The amount of thinning in the case of the following arm was much more striking. At a distance of two-thirds of the length of the arm it commenced to leave the outside edge, continuing gradually, and producing "the appearance of a luminous angle, regular and very pointed, the apex of which joined to the disk of the planet." Observed again on May 21, the following arm showed a protuberance situated near Cassini's division. In M. Bigourdan's own words, the above appearances could be produced by an "elevation of the level edging the separation of Cassini, and producing on the opposite face a luminous pad which would nearly double the apparent thickness of the ring."

GEOGRAPHICAL NOTES.

Petermann's Mitteilungen for June contains the long-expected account of Emin Pasha's return expedition to the equatorial lakes, written by his companion, Dr. Stuhlmann. Leaving Kahura in March 1891, they traversed an unknown region to the southern shore of Lake Albert Edward, which they followed round its western side, and marched as far north as the Ituri in 2° 13′ N. Here the party had to turn. Emin met a number of his old followers living near Kavalli, on Lake Albert, and many of them joined his expedition. The return journey was disastrous. An outbreak of small-pox made it necessary to divide the expedition; Emin was left behind, while Stuhlmann went on with those able to travel and reached the German station of Bukoba on Lake Victoria in February 1892. The scientific observations made necessitate certain corrections on the map of this part of Africa. Mount Mfumbiro is further west than originally supposed, and may even lie within the boundaries of the Congo State. It is a volcanic chain, one of the peaks of which, Mount Virungo, is apparently still active. Stuhlmann gives the level of Lake Albert Edward as 2750 feet instead of 3307 as determined by Stanley.

Sir William Macgregor continues to give proofs of remarkable energy as an explorer, and of tact and skill as Administrator of British New Guinea. In the early part of this year he has been engaged in a series of journeys through the south-eastern districts of the possession, and everywhere he has found the natives peaceful and friendly. In a recent coasting trip he passed several islands, which at first sight appeared uninhabited, but on landing he discovered that this appearance was due to their singular configuration. A narrow belt of gently sloping land led from the sea to a steep wall of coral rock, from 300 to 400 feet high, from the summit of which an undulating plateau was seen dipping inland. Here the villages were built, from 50 to 100 feet below the level of the encircling rim, and sheltered from the trade-winds. Sir William considers these islands to be upraised atolls, modified in most cases by subsequent wave action on the shore strips.

Lieutenant T. H. Barnes, on behalf of the Bolivian Government and the Argentine Geographical Society, is investigating the navigability of the Rio Otuquis, a tributary of the Upper Paraguay, in the hope of opening a new route for Bolivian trade.

Lieutenant Mizon, compelled by the passive resistance of the Royal Niger Company to relinquish his projected journey by the Benué to Lake Chad, has (according to *La Politique Coloniale*) crossed the watershed to the Congo Basin, and on his way from the Benué to the Sangha, traversed the hinterland of the German Cameroon colony, one of the rapidly-shrinking blank spots on the map of Africa. Reports from Tripoli state that Captain Monteil is pushing on from Kano, in Sokoto, to Bornu and Lake Chad.

The collection of educational appliances, books, atlases, &c., made by Mr. J. Scott Keltie on behalf of the Royal Geographical Society in 1885, has been lent to the Teachers' Guild of Great Britain and Ireland, in whose rooms at 74 Gower Street it has been admirably arranged by Miss Busk. This collection, which after its original appearance in London was shown in most of the large towns in the country, has never been more effectively displayed. When first brought together, the inferiority of the British school atlases and text-books to the German and French productions was very marked; but during the last seven years English publishers have made great advances, and several of the newer and better publications have been added. It would be most desirable if the department of English books, maps, and geographical appliances could be made thoroughly representative, so that teachers would have a real opportunity of comparing the best work of 1892 with that which was current in 1885.

Mr. H. J. Mackinder, Reader in Geography at Oxford, has recently returned from a brief visit to the United States, where he has been devoting special attention to the state of the higher geographical teaching. In many respects the American Colleges are in advance of the corresponding institutions in this country, and geography is attracting increased attention on the part of some of the most energetic and progressive educationists.

COUNT PFEIL, who recently passed through London, *en route* for the Cape of Good Hope, is about to conduct a party of emigrants to Walfisch Bay, in the hope of colonising the adjacent parts of German South-West Africa.

Two pillars, erected by Diogo Cão, the first Portuguese explorer on the west coast of Africa, have recently been brought back to Lisbon. An interesting circumstance is the discovery on the pillar brought from Benguela of an inscription showing that the coast had been traced so far in 1482, two years earlier than the date usually assigned.

THE IRON AND STEEL INSTITUTE.

THE annual meeting of this institution was held on Thursday and Friday of last week, at the Institution of Civil Engineers, Sir Frederick Abel, the President, occupying the chair. After the reading of the Council's annual report Sir Frederick Abel delivered his Presidential address. He began with a reference to the losses which the Institute had sustained during the year by the death of some of its eminent members. He spoke especially of the solid services rendered to science by the late Duke of Devonshire. The Duke's wise munificence in the establishment of the Cavendish Laboratory in Cambridge University, and the important part he took in the labours of the Royal Commission on scientific instruction and the advancement of science, were described as "illustrations of his active participation in a movement of most vital importance to the maintenance of our position and influence among nations." Sir Frederick also referred to the Duke's ready consent to fill the post of first president of the Iron and Steel Institute as a proof of his appreciation of the high importance to be attached to the successful foundation of an organization of which he predicted that it would prove "a powerful instrument for the advancement and progress of the iron and steel trade of Great Britain, by promoting intercourse and interchange of knowledge between its members"—a prediction which was speedily and amply fulfilled. In his introductory address the Duke had discussed the development of iron-manufacture in most interesting and comprehensive fashion. In referring to the most extraordinary mineral wealth of the United States, he pointed out that although in 1867 the production of pig iron in America had risen to nearly 1,350,000 tons (of 2240 lbs.), the price of labour did not warrant the belief that there was any immediate prospect of the United States competing with the iron-producing countries of Europe in the open markets of the world.

Sir Frederick continued:—

A very interesting report upon the state of iron manufacture was presented by Sir Lowthian Bell to the British Association at its meeting in Dundee in 1867. A critical examination was made therein of the relative position of ourselves and Continental nations as iron manufacturers, *à propos* of the Paris International Exhibition of that year; but in the encouraging view which that eminent authority presented of our position at the period named he was not led to make any reference to the prominence which the United States were beginning to assume among iron-producing countries. After the lapse of twelve years, however, the production of pig iron in the States had been doubled, while in another ten years it had reached a figure approximating to the average production in Great Britain during the past ten years.[1]

Viewed from our present standpoint, the observations made by our first President in his opening address of 1867, regarding the development of the manufacture of steel, are very interesting. The Duke pointed out that, "owing to recent inventions and improvements, steel had acquired an importance greatly exceeding that which it previously possessed." After referring to the then prevalent views regarding the nature of steel, and to its production by the cementation process, the puddling and the mixing processes, and the partial decarbonisation of cast iron by blowing air into pig iron melted in a charcoal hearth, he dwelt upon the interest with which the development of the Bessemer process had been watched by the iron-making world, upon the *promise* "which that process afforded of furnishing a supply of steel suitable for many most important purposes upon a scale and at a price hitherto unknown," and upon the association of the names of Joseph Heath with the first employment of manganese in steel manufacture, and of Robert Mushet with the important part played by manganese-alloys in the development of the Bessemer process. While the approaching expiration of the first Bessemer patent was referred to as likely to tend to an increase in the demand for its products, the limits which the then existing knowledge placed upon the application of the process were pointed out, and the advantages of the puddling process dwelt upon. It is interesting to note that, at any rate in Germany, these advantages have not yet been dispelled, in spite of the great revolution which the Bessemer and open-hearth processes have effected in the applications of wrought iron and steel. On the other hand, the importance which steel had acquired through the practical development of the Bessemer-process, at the date of our first President's address, was but an indication of the new era upon which the iron and steel industries were about to enter. In that year the produce of Bessemer-steel in the United Kingdom was only 160,000 tons, while open-hearth steel was not yet a staple product; in 1890 the British production of Bessemer steel exceeded two millions of tons, while that of open-hearth steel exceeded 1·5 millions of tons.[1]

A statement made in the Duke's address of 1869, that, so far as existing knowledge went, the Bessemer process was of limited application, as only certain kinds of iron were susceptible of successful treatment by it, affords, by a comparison with the present condition of things, an interesting illustration of the continuous progress made in the successful application of advances in scientific knowledge to practical purposes. The success which crowned the efforts of Thomas, Gilchrist, Snelus, and others to render the Bessemer- and open-hearth processes efficient in their application to ores, the successful treatment of which by them appeared well-nigh hopeless in the earlier days of the Iron and Steel Institute's existence, has recently been very prominently before the public, and the members will certainly receive with special interest the communication which the Director of Naval Construction has promised us on experiments with basic steel.

In the discussion which took place at the meeting of the Institute of Naval Architects last year, *à propos* to a paper by M. J. Barba on recent improvements in armour plates, it became evident that the public were far better instructed as to progress made in such directions as this by other nations than as to advances made by ourselves; such information as Mr. White feels warranted in affording us with respect to our progress in practical experience on the merits of basic steel as applied to shipbuilding and other naval purposes will therefore be very welcome.

From the United States interesting accounts have reached us of a continuation of the experiments with armour plates 10½ inches thick, which were commenced at Annapolis in September 1890, when an all-steel and a nickel-steel plate, from the Creusot works, were contested in comparison with a compound plate of Cammel's make. Of these, the nickel-steel plate was considered to have shown itself somewhat superior to the all-steel plate, and very decidedly superior to the compound plate; and it is stated that Congress showed its appreciation of the importance of this result by appropriating a million dollars to the purchase of nickel ore. The second and third series of trials have been carried out at the Naval Ordnance Proof Ground at Indian Island, near Washington. The plates fired at in October last, constituting the second series of three, are described as a high carbon nickel-steel plate from the Bethlehem Iron Company, one of low carbon nickel-steel from Carnegie, Phipps, and Co.'s works at Pittsburg, and a so-called "Harveyised" plate of low carbon steel from the Bethlehem works. The description given of the Harveyising process identifies it as being a case-hardening or partial cementation treatment, the surfaces of the steel plate being hardened by carbonization (and by a supplementary chilling process), and the increase in carbon dying away towards the interior of the mass. In the trials of these plates, that of high carbon nickel-steel appears to have stood the best, but the effect of the Harveyising process upon the powers of resistance of the low carbon steel plate seems to have afforded indications of beneficial effect such as to warrant the application of the process to nickel-steel plates included in the third series, fired at last November, and which comprised a high carbon nickel-steel plate from Carnegie, Phipps, and Co., a low carbon Harveyised nickel-steel plate from the same makers, and a high cabon Harveyised nickel-steel plate from the Bethlehem Company. In all the nickel-steel plates, including that from Creusot tried in 1890, the amount of nickel in the metal appears to have been a little above 3 per cent.

---

[1] Mr. Robert S. M'Cormick, Resident Commissioner for Great Britain for the Chicago Exhibition of 1893, in a paper recently communicated to the Society of Arts upon the future trade-relations between Great Britain and the United States, gives the following figures as demonstrating that the British iron and steel industry has been outstripped in magnitude by that of the United States. In 1890 the produce of pig iron in America was 9.202,703 tons against 7,875,130 tons in the United Kingdom; of manufactured iron, including rails, 2,820,377 tons were produced in America against 1,923,221 tons in Great Britain, and, of Bessemer steel, 3.688,871 tons were American produce, while the production in the United Kingdom amounted to 2,014,843 tons.

[1] 1891 appears to have witnessed a very remarkable falling off in the production of Bessemer steel, to the extent indeed of about 35 per cent., while the production of open-hearth steel exhibits a reduction in the past year of only 3 per cent.

Care seems to have been taken to render all conditions attending the trials as uniform as practicable, with this not unimportant difference, that very much less time was allowed to elapse, in the second and third trials, between the firing of the successive rounds than in the first experiments.

A careful consideration of the results led the Board, of which Admiral Kimberley was President, to the unanimous conclusion that the high carbon Harveyised nickel-steel plate was the best, but that one part of the plate was much superior in resisting powers to the other, which was ascribable apparently to a want of uniformity in the Harveyising or carbonising treatment. The official report is also said to have recorded the unanimous opinion of the Board that both the high carbon nickel-steel Harveyised plate and the high carbon nickel-steel untreated plate were superior to the Creusot nickel-steel plate tried in 1890.

Further trials will shortly be made of high and low carbon nickel-steel Harveyised plates, to be supplied by Carnegie, Phipps, and Co. From published analyses it appears that the high carbon nickel-steel plate manufactured by that Company contained 0·45 per cent. of carbon and 0·65 per cent. of manganese, and the low carbon plates of nickel-steel, 0·26 per cent. of carbon and 0·75 per cent. of manganese.

The *New York Sun*, with what appears, from the reported results, to be very justifiable sentiments of pride, winds up an account of the results arrived at with the remark that they show that America now stands at the top in the excellence of her ship-armour; and certainly our friends of the Bethlehem and Pittsburg Steel-works are to be warmly congratulated upon their achievements in this new direction.

Although the trials in the United States seemed to establish a marked superiority of nickel-steel plates over the compound plates of J. Brown and Co.'s manufacture, it is interesting to notice that this eminent firm is gallantly striving to maintain the high position which exhaustive trials had secured to that form of plate, as efficient armouring for ships of war, and that recent trials at Shoeburyness and at Portsmouth of experimental compound plates which have been submitted to a supplemental process devised by Captain Tressider, late Royal Engineers, seem, so far as I can learn, to have demonstrated that powers of resistance and endurance, much exceeding those of the compound plates tried in the United States and in the Ochta experiments of last year, can be secured to these structures. I have reason to hope that we shall receive a communication ere long on the interesting results which are being obtained in this direction.

My reference to the rapid advance which has been made in the United States in the manufacture of armour plates will recall to the minds of many here present the memorable visit of the Institute to America in 1890. The valuable record of that visit presented to us a few months ago by the American Institute of Mining Engineers, in the form of a portly volume, embracing full accounts of the proceedings and the papers read and discussed at the international meetings at New York and Pittsburgh, constitutes an important work of reference, as well as an interesting memento of one of the most notable events in the history of our Institute. And now, thanks mainly to the self-sacrificing exertions of our much-esteemed past President, Sir Lowthian Bell, we have been able to match this American volume with a companion work, the interest and value of which it would, I venture to say, be difficult to over-estimate. The series of monographs by Sir Lowthian Bell and other highly competent authorities which are embraced in this special volume (aptly named "The Iron and Steel Institute in America"), will certainly receive careful study—productive both of profit and of pleasure, at the hands not only of members of the Institute, but also of our transatlantic friends who so cordially received us; and our warmest thanks are due to the joint authors of this work, and especially to Sir Lowthian Bell, who, besides contributing some of the most valuable of its contents, undertook the arduous task of editing the volume; and I beg leave heartily to congratulate him upon the realization of his wish, that the completed work should make its first appearance in public at this meeting.

An interesting illustration afforded by the inaugural address of the Duke of Devonshire in 1869 of the advance made in the knowledge at the disposal of the iron and steel maker, is found in his observations on the relations of carbon to iron and steel, a subject which I had occasion to discuss in some detail in my opening address last year, in reference to the then recent interesting investigations in that direction; a subject on which we may still hope to have further light thrown by the continued researches of Osmond and others. The very complete and systematic manner in which existing knowledge on this subject is treated in the first part, recently published, of Dr. Hermann Wedding's new edition of his *Handbuch der Eisenhüttenkunde*, calls for the highest commendation.

The importance of pursuing the investigation of problems such as the conditions most favourable to economy in the use of fuel in the blast furnace, and conditions to be fulfilled in the form and dimensions of the furnace for ensuring efficiency and economy of working, were dwelt upon by the Duke of Devonshire in his comprehensive address, and reference was made to the elaborate inquiry into the chemical operations occurring in the blast furnace upon which Sir Lowthian Bell had then for some time been engaged. The interesting results arrived at by him, and the instructive discussions to which they and the conclusions based upon them gave rise, are memorable illustrations of the progress in the application of scientific research and reasoning to the study of metallurgic operations, in the promotion of which the Iron and Steel Institute has of late years played an important part, and the most recent outcome of which, in connection with the production of pig iron, is to be found in the remarkable achievements recounted by Mr. Gayley in his paper on the development of American blast furnaces, which was one of the most noteworthy communications dealt with at the New York meeting in 1890.

In directing attention to that paper in my address a year ago, I spoke of the reference made by Mr Gayley to the importance of the elaborate series of investigations carried out, nearly a quarter of a century ago, by Sir Lowthian Bell on the chemistry of the blast furnace. I have had occasion since then to refresh my memory with regard to the ground covered by the work which our ex-President then carried out, and I must freely confess that I had no recollection of its extent nor of the mass of interesting and important experimental data accumulated by him, until I lately referred to the comprehensive and systematic investigations on the chemical phenomena of iron-smelting, which he communicated in detail to the meeting of the Institute at Merthyr in 1870. His paper on the chemistry of the blast furnace, to which I had the pleasure of listening at the Chemical Society in 1869, deals with the circumstances and conditions attending the union of iron with carbon in the blast furnace, and gives interesting results bearing upon the question of the temperature at which carbon is deposited in a finely-divided state in ironstone when it is exposed to the waste gases, rich in carbonic oxide, of the blast furnace; and the subject is discussed more definitely, by the light of additional experimental information, in Sir Lowthian Bell's admirable work on the "Principles of the Manufacture of Iron and Steel," published in 1884. He there demonstrates the readiness with which carbon is desposited in iron sponge from carbonic oxide at temperatures up to a dull red heat, examines into the question whether the presence of iron in the metallic state in iron ore is indispensable for determining the dissociation of carbonic oxide, and, after concluding in the negative, and demonstrating that metallic iron is not more active in this respect than its oxide, he refers to trials made by him of the power of several other metals and metallic oxides to effect the dissociation of carbonic oxide.

In the researches communicated in 1870 to the Merthyr meeting, the whole of these experiments are given and discussed, and it is to be regretted that the interesting results arrived at did not receive greater publicity than they met with in the Transactions of a young technical Institute, then comparatively unknown in the scientific world, and in which the results of original scientific research would scarcely be sought for.

Without venturing to enter into the details of these researches, I may mention that experimental evidence favoured the conclusion that the carbon-impregnation of an iron ore by dissociation of carbonic oxide takes place at as low a temperature as de-oxidation, which, in the case of Cleveland ore, occurs at 200° to 210° C. (392° to 410° F.), and that freshly reduced spongy iron, at about that temperature, reduces carbon from carbonic oxide to an extent corresponding to 20–24 per cent. of its weight, but that, as the temperature approaches a red heat, the deposition of carbon diminishes considerably in amount.

The results of many experiments with other metals and their oxides showed that zinc, tin, chromium, and silicon, and their oxides are neither reduced by carbonic oxide at a temperature of about 420° (that of melted zinc), nor give rise to deposition of carbon; that copper and lead are reduced at temperatures up to a red heat, without deposition of carbon; that the higher manganese oxides are reduced to protoxide below a red heat without impregnation by carbon; but that nickel, and in a smaller degree cobalt, suffer reduction from their oxides, with deposition of carbon.

Sir Lowthian Bell, while conducting his experiments at temperatures considerably below those prevailing at the particular positions in the blast furnace where the production of pig iron was believed to be effected, did not have recourse to so low a temperature as that at which Messrs. Mond, Langer, and Quincke, after having demonstrated (what appeared, in the absence of an acquaintance with Bell's results, a novel observation) that carbon was separated from carbonic oxide by passing the gas over nickel at a high temperature, found that this metal actually entered into the composition of the gas. Thus they started from the point, in this particular direction, up to which Sir Lowthian Bell had carried his observations twenty years previously, and obtained the remarkable nickel-carbon-oxide compound referred to by me in my address last year, which they have since succeeded in producing upon so considerable a scale as to afford prospect of its acquiring industrial importance.

In the description of their earliest results, they stated that attempts to produce similar combinations of carbon oxide with other metals, including iron, had failed. By persevering with research in many very varied directions, and especially with iron, they at length succeeded in volatilizing notable, although small, quantities of the latter metal in a current of carbonic oxide, by using the finely-divided pure iron obtained by reducing the oxalate in a current of hydrogen at the lowest possible temperature (about 400° C.), by allowing the product to cool in hydrogen to 80°, and then by passing a current of carbonic oxide over the spongy metal. The gas, after this treatment, was found to impart a yellow colour to a colourless flame, and if conducted through glass tubes heated to between 200° and 350° C., it deposited a metallic mirror; at a higher temperature it furnished black flakes, which analysis showed to contain 79·30 per cent. of carbon. The quantity of iron- and carbon-oxide compound produced in this way was very small; by passing 2½ litres of carbonic oxide per hour over the metal (the latter being from time to time reheated in a current of hydrogen), the issuing gas contained not more than 0·01 grm. of iron, equal to less than 2 c.c. of the gaseous iron-compound in a litre of the carbonic oxide.

The gas-mixture, when passed through benzine or heavy mineral- or tar-oils, was partially deprived of the iron compound, and the result of examination of solutions of this kind led to the conclusion that the gaseous iron combination, analogous in composition to the nickel-carbon-oxide compound (or nickel-tetra-carbonyl), had been found, and that its formula was $Fe(CO)_4$.

In continuing their researches, Mr. Mond and Dr. Langer have succeeded in obtaining the iron compound in the form of a liquid of spec. grav. 1·4664 (at 18° C.), which distils without decomposition at 102°·8 C., and solidifies below 21° into yellow needle-shaped crystals. It is slowly decomposed by exposure to air, and when its vapour is heated to 180°, it is completely decomposed into iron and carbonic oxide. Analysis and the determination of its vapour density show the composition of the liquid to be represented by the formula $Fe(CO)_5$, and Messrs. Mond and Langer have therefore called the compound *ferro-penta-carbonyl.*

If exposed to light in a sealed vessel for several hours, it deposits gold-coloured tabular crystals having a metallic lustre like gold when dry, but becoming brown by gradual decomposition when exposed to air. These crystals appear to contain a slightly smaller amount of carbonic oxide than the liquid compound from which they are deposited. Mr. Mond and his co-laborateurs are still actively engaged in pursuing the researches which have brought to light the formation of these remarkable metallic compounds, whose discovery and properties suggest possibilities in several directions of technical chemistry which will doubtless lead to interesting investigations.

The first report made by Prof. Roberts-Austen to the Alloys Research Committee of the Institution of Mechanical Engineers, bearing upon the particular investigation undertaken by him at their request, although little more than introductory in its character, is full of interest, and of importance not only on account of the valuable information it furnishes regarding the method of investigation adopted by him and of the preliminary results attained by its agency, but also because of the interesting discussion elicited by its presentation to the Institution of Mechanical Engineers at their meeting last autumn.

At our annual gathering a year ago we had the advantage of receiving from Prof. Roberts-Austen a description of the autographic method adopted by him for recording the results indicated by the Le Chatelier pyrometer, the efficient operation of which I had an opportunity of witnessing as a member of the Alloys Research Committee. We also heard from Sir Lowthian Bell that he had already successfully and very usefully applied this pyrometer to determine the temperature of the blast entering a furnace at a considerable distance from the point of observation. We shall, I trust, have the advantage of learning the results of further experience by Sir Lowthian and others in the practical application of this much-needed instrument in conjunction with the automatic recording system used by Prof. Roberts-Austen; the observations made by the present President of the Institution of Mechanical Engineers, by Mr. Henry M. Howe, of Boston, and by others at the discussion of the Professor's report, demonstrated that several valuable applications were already being made of the Le Chatelier pyrometer and the system of continuous record of its indications. While it is satisfactory to me, as one of the earliest to use the ingenious pyrometer designed by my distinguished friend the late Sir William Siemens, to note that its trustworthiness as an indicator of temperatures up to 500° C. has been vindicated by the work of Messrs. Callendar and Smith, the accuracy and sharpness of the indications of Le Chatelier's pyrometer, the simplicity of its character, and the well established trustworthiness of its results at temperatures of over 1000° C., render it decidedly more valuable to the practical metallurgist, as well as to the scientific investigator, than any instrument of the class hitherto available. We shall none the less be glad to hear what Mr. Callendar has to tell us on the present occasion with regard to the results of his persevering and, I believe, successful labours in discovering and eliminating the defects of construction which served to destroy the confidence placed, in the first instance, on the indications afforded by platinum pyrometers.

The tendency of the discussion following the reading of Prof. Roberts Austen's report, which was shared in by Mr. Robert Hadfield, Mr. Henry M. Howe, and by some others whose right to criticism was beyond dispute, was to emphasise the necessity for caution in the application of theoretical views, regarding the laws which regulate the mechanical or physical properties of metals, to predictions as to the influence upon the properties of metals, such as iron, of particular impurities. I believe no one will be disposed to differ from the view expressed on that occasion by Prof. Arnold, that, for a thoroughly comprehensive examination into "the effects of small admixtures of certain elements on the mechanical and physical properties of iron, copper, lead, and other metals," it is indispensable to combine different lines of investigation with the particular one which Prof. Roberts Austen has so far prosecuted with very promising results.

The fame which Mr. Gruson has acquired in connection with the production of chilled iron structures, for land defence, presenting marvellous powers of resistance, must cause members of the Institute to look forward with much interest to the communication which has been promised us by the director of the Gruson Works, Mr. E. Reimers, on the manufacture and application of chilled cast iron, a subject with which, especially in regard to the selection of varieties and mixtures of iron suitable for securing a structure of metal essential to the attainment of combined toughness and hardness in armour-piercing projectiles, I was much concerned in the days of my much-lamented friend, the late Sir William Pallisser.

Another subject to which I devoted considerable attention twenty-three years ago, in co-operation with the late Dr. Matthiessen, bears directly upon some very interesting results which will be brought to your notice by my old and valued friend Colonel Dyer, of the Elswick Ordnance Works. In 1863 Dr. Matthiessen communicated to the British Association the results of some interesting researches into the chemical nature of alloys, which he followed up in 1866 with a preliminary report on the chemical nature of cast iron. In this memoir, after drawing a comparison between the physical deportment of what he terms the alloys of carbon and iron, and those of such alloys as are produced by copper with zinc and with tin, he discusses in some detail the question whether carbon exists in combination with iron, in cast iron, and expresses himself in favour of the view that white iron is not actually a chemical combination of carbon with the metal, but rather a solidified solution in it of carbon, while grey iron is a solidified solution of the same kind, with carbon mechanically intermixed. But while he supports this hypothesis by certain analogies between the specific electric conducting power of different varieties of iron and of alloys of other metals, he proposes to test the validity of his views by preparing pure iron, alloying it with various proportions of carbon, examining the physical and chemical properties of these alloys, and afterwards investigating the properties of alloys of the pure metal with various other metals and non-metals. Matthiessen's persevering endeavours to elaborate a process for the preparation of pure iron, which extended over three years, were at length crowned with success, and in 1869 I was engaged with him upon experiments with metal, obtained in the form of sponge, containing as its only impurity a minute trace of sulphur. This iron was prepared by fusing together perfectly pure and dried ferrous sulphate and sodium sulphate, completely washing the crystalline oxide thus obtained, and then reducing it to metallic sponge by heating it in thoroughly purified hydrogen. The sponge metal was welded together in the cold by powerful compression, for certain experiments; for others it was fused in very carefully prepared lime-crucibles. The experiments which it was hoped to undertake with this pure material, in the directions I have indicated, were arrested almost at their commencement by Dr. Matthiessen's death, and by the all-engrossing nature of my official labours. The process, which was elaborated with such trouble, may perhaps prove useful in connection with the investigation which Prof. Roberts-Austen has undertaken for the Alloys Research Committee of the Institution of Mechanical Engineers; but it appears to me that there is good prospect of procuring iron sufficiently pure, at any rate for certain of the experiments (when carried out upon a practical scale) which will form part of these investigations, by the very simple mode of procedure which Colonel Dyer has adopted in the production of iron containing only traces of carbon and silicon, no phosphorus, and less than two-hundreths of one per cent. of sulphur, and which affords a very interesting instance of the application of the basic furnace.

In concluding these few observations, I cannot forbear once more referring to the interesting address delivered to the members by our first President twenty-three years ago, in order to point out how strikingly its peroration illustrates the progress which has been made in the development of the steel industry during the past twenty-two years. While forcibly dwelling upon "the extraordinary influence which the manufacture of iron had come to exercise on the condition of society throughout the civilized world," the writer gives no indication of the part then played, or destined to be played, by *steel* in that civilizing influence. Even seven years later, when steel-manufacture had advanced with rapid strides, there was still great hesitation in adopting it for some of the most important purposes to which iron was applied; thus Sir Nathanial Barnaby wrote at that time, "Our distrust of steel is so great that the material may be said to be altogether unused by private shipbuilders." Yet, a few years afterwards, it had come to pass that the examples of the marvellous development in the applications of iron, to which the Duke referred in illustration of his statements, constituted the very directions in which the steel manufacturer has accomplished his most prominent achievements, and in which the use of iron is becoming a memory of the past.

The following was the list of papers to be read:—On experiments with basic steel, by W. H. White, C.B., F.R.S., Director of Naval Construction; on the production of pure iron in the basic furnace, by Colonel H. S. Dyer, of Elswick; on experiments on the elimination of sulphur from iron, by E. J. Ball, Ph.D., and A. Wingham, F.I.C.; on platinum pyrometers, by H. L. Callendar; on the manufacture and application of chilled cast iron (Gruson's system), by E. Reimers, of Magdeburg; on valves for open hearth furnaces, by J. W. Wailes; on the calorific efficiency of the puddling furnace, by Major Cubillo, of Trubia Arsenal, Spain; on a practical slide rule for use in the calculation of blast furnace charges, by A. Wingham, F.I.C.; notes on fuel, and its efficiency in metallurgic operations, by B. H. Thwaite.

The whole of these papers were read except that by Major Cubillo.

Mr. White's was the first contribution taken. His paper was founded on a number of experiments made at Pembroke Dockyard, with a view to determine the suitability of steel made by the basic process for ship-building purposes. It would be useless to attempt to summarise the results of the large amount of information contained in the paper, and in the tables, which formed an appendix to it. As a general fact, it may be said that basic steel no longer labours under the disadvantages that attended its early days, when it was undoubtedly unfit to be used as a ship-building material. The importance of the basic process to this country can hardly be overrated. The manufacture of steel on the original acid process demands a pig low in phosphorus, and this can only be prepared from a special ore, such as the hematites of Cumberland and other parts. Unfortunately, the deposits of such ore in the British Isles are very limited in extent, and it is for this reason that we have been, for years past, importing vast quantities of steel-making ore from the neighbourhood of Bilboa in Spain. This means a heavy item for freight; and it is a question whether we could, in England, stand the competition of Spain, if that country once organized her steel-making resources on a sound footing. But in any case it is desirable we should depend, as little as possible, on foreign countries for raw material, when we have such vast stocks within our own borders. In the ores of the Cleveland district and other parts, we have such deposits, but the ore contains a comparatively large percentage of phosphorus, which entirely unfits it for the old acid process of steel-making. The basic process, however, is designed to enable phosphoric pig to be used, and to judge by Mr. White's paper a fair measure of success has been attained in this direction. It would have been interesting if the paper had given details as to the pig from which the steel was made. Mr. Martell has said that no steel to meet Lloyd's requirements has been made from pig containing 3 per cent. of phosphorus, and that the basic steel which has been successful has been made from an ore low in phosphorus. It is, however, not the bulk of the phosphorus which is difficult to eliminate, but the last part, and Sir Lowthian Bell stated that he would be glad if the pig of his district did contain 3 per cent. of phosphorus instead of about half that quantity, as it would then produce a slag more valuable for fertilizing purposes. However this may be, it would have been satisfactory to have had full analyses of pig to attach to particulars of physical tests so well authenticated as those now given to the engineering world by Mr. White's paper. Another point upon which it is desirable to get information is, which process gives the best results in working on the basic principle? We have always considered it a settled matter that the open-hearth furnace was superior to the converter in this respect, so far as the quality of the product is concerned, and the discussion of last Thursday, on the whole, tended to confirm this opinion. The opposite view, however, was advanced by more than one speaker whose words should carry weight; and there is also the question of cost and quickness of production to consider. On the whole, it would seem, therefore, that the problem as to whether the converter or the open-hearth furnace should be used is still an open one; doubtless it will be settled in this case, as before, by the special requirements of the metal to be produced. As we have said, we cannot reproduce even a brief abstract of Mr. White's paper, but we can give one or two figures. One sample of basic Bessemer had a tensile strength of 30·6 tons per square inch, and an extension in 8 inches of 26 per cent. Of some pieces tested after annealing the tensile strength was about 28 tons, with an elongation of 25 per cent. One sample of basic open-hearth showed 31·3 tons per square inch tensile strength and 26·2 per cent. extension in 8 inches. We quote these figures as showing the best results, and to serve as a guide; it is doubtless unnecessary to say that they are not conclusive standing alone. The riveting tests given are valuable, but these are of a nature which cannot be epitomized.

Colonel Dyer's paper might well have been longer, as the subject of it is one of considerable importance. Pure iron is a substance at any rate difficult to get. Sir Lowthian Bell has said he has never met with absolutely pure iron. Commercially pure iron, or what might be called practically pure iron, is not uncommon. Colonel Dyer's object was to obtain a pure iron in order to determine the value of alloys. By working on the lines which he had followed, the author hoped that pure iron and steel may be produced at reasonable cost. In the first experiments the furnace was charged in the ordinary manner with pig and scrap of fairly good quality, and the charge was worked slowly, care being taken to keep the slag well saturated with lime by liberal additions of limestone. The phosphorus was reduced during the process, but the result left much to be desired in other respects. Charges composed of from one-half to four-fifths of good scrap, and one-half to one-fifth of good Swedish pig were then worked very quickly, and a remarkably pure iron was obtained, of which the following was the result of analysis:—

Combined carbon	trace
Silicon	·005
Manganese	trace
Phosphorus	trace
Sulphur	·015

This iron could only be forged in small pieces, even with the greatest care, and therefore no results could be given as to its mechanical properties. Dr. Hopkinson had determined the magnetic properties of the metal, but the results are to be reserved for the Royal Society. Speaking generally, it has been found that the metal is more easily magnetized for small magnetizing forces than any other metal hitherto tested; its coercive force is less, its magnetization is greater, than any other sample experimented with. The next stage of Colonel Dyer's experiments had for their object the utilization of ordinary scrap steel, and the production, in the basic furnace, of steel high in carbon and low in phosphorus, and at the same time to decrease the wear and tear of the furnace. The principle of the process consists in melting scrap with carbonaceous material, and the results of the experiments have shown that when a pure carbonaceous material and ferro-manganese free from phosphorus can be obtained there will be no difficulty in producing a pure carbide of iron containing only sufficient manganese for forging. The author next described the method by which the process was carried out. Nine consecutive charges were worked, with the object of producing steel containing varying percentages of carbon, to test the value of the process. The following table gives the chemical analyses and the mechanical properties of the steel of these charges:—

Tensile Tests.					Chemical Analysis.				
No.	Yield.	Break.	Elongation.	Fracture.	C.C	Si.	Mn.	P.	S.
			Per cent.						
1	14·0	22·7	44·0	F.	·11	trace	·21	trace	·030
2	14·0	23·0	41·5	F.	·10	,,	·21	,,	·030
3	18·0	27·5	32·0	F.	·16	·020	·40	·018	·022
4	21·0	30·0	33·0	F.	·21	trace	·39	·014	·026
5	20·0	31·2	32·5	F.	·25	·014	·43	trace	·019
6	23·0	34·0	26·0	F.	·24	·018	·50	·019	·024
7	25·0	35·4	20·0	F.	·30	trace	·38	·019	·017
8	25·0	43·2	18·5	F.	·53	·012	·54	·016	·028
9	24·0	45·3	14·5	F.G.	·50	·031	·60	·009	·026

The paper by Messrs. Ball and Wingham, on the elimination of sulphur, contained the results of experiments thoughtful and suggestive in themselves, even if they do not show the iron and steel maker any immediate results which he may apply. The authors found that potassium cyanide placed on the surface of molten cast iron almost completely removed the sulphur. Owing to the extreme volatility of the cyanide, it was not found possible to reduce the quantity required to within practical limits, and efforts were therefore made to find some flux which would retain, when molten, a quantity of cyanide sufficient to effect the desulphurisation. Sodium carbonate, lime, and blast-furnace slag were in turn tried. It was found that the desulphurising action was greater when the flux consisted mainly of sodium carbonate than when a less basic lime slag was used; and that in the latter case the diminution in the percentage of sulphur varied directly with the amount of added cyanide. A table is given of the results of the experiments, the best condition being obtained when 200 grains of sodium carbonate and 100 grains of potassium cyanide were used to 2000 grains of metal, when the sulphur was reduced from 0·46 per cent. to 0·06 per cent. A further experiment with sodium carbonate alone—400 grains being added to 4000 grains of metal—the sulphur was reduced from 1·11 to 0·15 per cent. With caustic soda the sulphur was reduced from 0·15 per cent. to 0·02 per cent., which is a satisfactory result. The experiments also showed the facility with which sulphur is reduced when present in large quantities, and that it is the last part which gives difficulty in removing. Metallic sodium was introduced into the bath in the form of an alloy with lead, and this had the effect of entirely removing 0·18 per cent. of sulphur.

The paper by Mr. Reimers, which was the first read on Friday, the second day of the meeting, does not call for notice, excepting, perhaps, to remark that the Council of the Institute were to blame for not taking care that the author was informed beforehand that his contribution was not of a nature which should have been submitted in the form in which it was read. Mr. Callendar's paper on "Platinum Pyrometers" is a great contrast to the last-mentioned. The prominence given to the Le Chatelier pyrometer in this country, by Prof. Roberts-Austen chiefly, has led to renewed hope on the part of those who desire to measure higher temperatures. Mr. Callendar has been amongst those who have been giving attention to the subject, and the results of his labours, which are distinctly valuable, are given in his paper, to which we would refer all practically interested in the matter. His introductory remarks on air pyrometers are interesting, and may be read with advantage by those not already acquainted with this branch of the subject; but it is of the Siemens electrical resistance thermometer, known generally as the "platinum pyrometer," that he has most to say. It has been hitherto accepted that the platinum pyrometer was subject to the serious defect of changing its zero with use. The British Association Committee of 1874 discovered this, and it has since been amply confirmed as a fact. The Committee experimented chiefly with a pyrometer in an ordinary fire at moderate temperatures of about 800° C., and they found that the resistance increased continuously with heating, and that the wire underwent rapid deterioration. They also made some experiments and suggestions with a view to remedy this defect, but they did not succeed in overcoming it. This continuous change of zero is certainly the most serious practical defect that a pyrometer can have, and there can be no doubt that the report of the British Association did a great deal to destroy confidence in this method of measuring temperature.

We cannot do better than continue Mr. Callendar's communication on this part of the subject in his own words:—

"About seven years ago, when I began making experiments on this subject at the Cavendish Laboratory, Cambridge, I was at first very much surprised to find that the platinum wires which I used did *not* undergo continuous change, even when subjected to much more severe tests than those applied to the Siemens pyrometer by the Committee of the British Association. By making further experiments, however, with a sort of imitation Siemens pyrometer, I succeeded in reproducing at pleasure the effects they had observed, and in proving to my own satisfaction that these defects were not inherent to the method, but merely incidental to the particular form of instrument on which they experimented. I found that if the wire were properly protected from strain and from contamination, the pyrometers could be made practically free from change of zero, even at very high temperatures.

"The construction of the Siemens pyrometer has not, so far as I am aware, undergone any material change since 1874. The coil of platinum wire, which forms the sensitive part of the instrument, is wound on a clay cylinder, and packed in an iron tube from 5 to 8 feet long, and about an inch or so in diameter. I have here the fine wire and the clay cylinder from a pyrometer which was recently in use at the Royal Arsenal, Woolwich. I was informed that it had never been heated above 900° C., or 1600° F., but its resistance had increased some 15 per cent., corresponding to an error of about 100° F. in the temperature measurements. When the instrument was taken to pieces it was found that the wire was quite rotten and brittle in some places, and sticking to the clay cylinder. This, I think, is sufficient evidence that the clay, or some impurity contained in it, attacks the wire, otherwise the local nature of the action could not be explained, unless the quality of the wire used was very inferior.

"I have tried several materials on which to wind the wire, but have found nothing that answers so well as mica. The plan I generally adopt is to double the wire on itself, and wind it round a very thin plate of mica, in such a way that it only touches the mica at the edges. This method gives very good insulation, even at high temperatures, and, so far as I can discover, the mica has no action on the wire even at temperatures of 1200° C.

"Another defect of the Siemens pyrometer is the iron-containing tube. Metallic vapours of any kind will attack the wire readily, and will ruin the pyrometer. It is not probable that the iron itself will be appreciably volatile at temperatures below 1000° C., but it is very likely to contain several more volatile impurities. Vapours of copper, tin, zinc, &c., rapidly render the wire brittle and useless. A comparatively small trace suffices."

Mr. Callendar's wires were inclosed in glass, a material which naturally cannot be used for high temperatures. He finds that a hard-glazed porcelain tube does very well to protect the wire, at least up to temperatures of 1200° C. A silica tube would be better, but that the author has not succeeded in obtaining. He pointed out, however, that good porcelain is not so fragile as it is generally thought to be. He has only broken one tube, and that with a hammer. He hopes, however, ultimately to be able to produce a satisfactory silica tube. The remainder of the paper was taken up with a description of the indicating apparatus, but here, again, we must refer our readers to the original paper.

Mr. Thwaites's paper is of far too formidable proportions for us to deal with in anything like detail in this notice. He describes calorimeters, pyrometers, &c., and their uses. A good deal of the matter put forward is not altogether new.

Mr. Wingham's paper on the slide rule is of value to those interested in the practical working of blast furnaces.

Mr. Wailes's gas furnace valve has been designed to give an absolutely air-tight closing, an effect which is obtained by a water seal. Illustrations were given by means of wall diagrams.

The meeting was brought to a close with the usual votes of thanks.

The autumn meeting will be held in Liverpool, but the date is not yet fixed.

THE YEARLY ADMISSIONS TO THE ROYAL SOCIETY.[1]

The discussions that arose in connection with the revision of the Statutes of the Royal Society during the years 1890 and 1891, led me to endeavour to obtain definite data on which to found a trustworthy opinion as to the effect of the existing limitation of the number of yearly admissions on the eventual total strength of the Society, and the probable result of increasing the number beyond fifteen, the present limit.

The facts bearing on this subject, so far as I have been able to collect them from the records of the Society, are embodied in the tables annexed to this communication, for the proper appreciation of the significance of the figures in which a few preliminary explanations are necessary.

The anniversary of the Society being fixed for November 30 in each year, the customary record of the number of Fellows for any year refers to the number on that date. I have throughout regarded the date to which this number applies as being January 1 of the following year.

The annual election of Ordinary Fellows usually takes place in the first or second week of June in each year. I have considered the date to be January 1 of the same year.

The lapses, whether from death or other causes, have been treated as having occurred at the end of the calendar year in which they take place.

These assumptions have been made to simplify the various computations that the investigation required (which have been sufficiently troublesome as it is), and owing to the considerable period dealt with, forty-three years, the results will not, I believe, be sensibly affected thereby.

Unless it is otherwise specifically stated, the numbers refer exclusively to the *Ordinary Fellows*, elected at the regular annual meetings fixed for the purpose.

So far as I have been able to ascertain (for the earlier records in many particulars are defective), the number of Ordinary Fellows elected since 1848 has been 15 in each year, except on four occasions; in two years the number having been 14, and in two years 16: the average, therefore, is 15 yearly.

During the period since 1848, the number of *Royal* and *Honorary* Fellows has been about 5, and the *Foreign* Members about 50; these are included in the total number of Fellows shown in the annual reports of the Council, but will not be further considered in what follows.

The rules under which certain privileged classes have been admitted as Fellows, in addition to the *Ordinary* Fellows, have varied somewhat since 1848, but at present, apart from the persons eligible for the classes of Fellows above excluded, the only persons so privileged are Privy Councillors. The total number of *Privileged* Fellows elected since 1848 seems to have been 75, which for 43 years gives an average of 1·75 per annum.

Table I. contains a summary of the available data relating to the total number of Fellows since 1848.

The total number, excluding Royal, Honorary, and Foreign Fellows, at the commencement of 1848 was 768. I am not able to say how many of these were Fellows elected in the ordinary way, and how many were privileged, but this has no importance for my present object. From 1860 onwards the distinction between the three classes, those elected before 1848, Privileged Fellows, and Ordinary Fellows, is exhibited.

At the end of 1890, the total number of Fellows, excluding the Royal, Honorary, and Foreign Classes, was 463; of whom 26 were Fellows elected before 1848, 36 were Privileged Fellows elected since 1848; and 401 Ordinary Fellows elected since 1848.

Hence it appears that the reduction of number of Fellows, of the three classes last referred to, has been 305, and as the number of admissions of the Privileged class has not been very materially affected by the changes in the rules relating to them, it follows that virtually the whole of this large reduction is a consequence of the restriction, to 15, of the number of Ordinary Fellows elected yearly.

As the ages of the 768 Fellows who constituted the bulk of the Society in 1848 are not known, and as the conditions of election before that year differed materially from what they have been since, no very useful conclusions can be drawn from the rate of their diminution since 1848.

Assuming, however, that the number of Privileged Fellows in 1848 was, as is probable, about 50, there would remain 718 Ordinary Fellows, of whom in 43 years 692 lapsed, or at an average yearly rate of 2·24 per cent., that is rather more than 16 a year. This rate, as I shall show subsequently, does not differ greatly from that which has prevailed among the Ordinary Fellows elected since 1848, and it may therefore be presumed that the average age of the Fellows in that year did not differ greatly from the average age since.

Table II. gives, as far as available data admit, the ages at the time of election of all Fellows elected since 1848; and shows the number of years they severally survived, the average age at election, the number and average age of those who were alive in 1891, and the greatest and least ages of Fellows elected in each year.

From this table it will be seen that there has been a gradual small increase in the age at election; the average for the first 10 years having been 42·2; for the second 10 years, 43·0; for the third 10 years, 44·8; and for the last 13 years, 45·2.

The accuracy of these conclusions may be somewhat affected by the greater number of unknown ages in the earlier years, the age when unknown having been taken at the average of the group of years in which the election took place.

The least age at which any Fellow has been elected is 24, one such case being recorded. The average minimum at any election is slightly under 30, and the average maximum is rather over 63; one election at an age of 87 is recorded, and several above 70.

The oldest survivor of the Fellows elected since 1848, who alone are dealt with in this table, was 86 years of age in 1891.

---

[1] "On the Probable Effect of the Limitation of the Number of Ordinary Fellows elected into the Royal Society to Fifteen in each Year on the eventual Total Number of Fellows." By Lieut.-General R. Strachey, R.E., F.R.S. Read at the Royal Society on May 12, 1892. This paper was accompanied by four tables, presenting summaries of the author's results.

The average age at election was 43·9, and the average age of all the Fellows in 1891 was 58·4.

Table III. records the numbers of Ordinary Fellows elected in each year, and remaining alive in each year after election, until 1891.

From this it will be seen that during the last ten years the numbers have increased by 46; in the previous ten years the increase was 68, or 22 more; and in the ten years still earlier the increase was 111, or 43 more than the last. If the decrease of growth for the ten years after 1890 takes place in a similar ratio to that which took place between 1870–80 and 1880–90, we might anticipate an increase of only 11 up to 1900, or probably a smaller number.

In order to obtain a satisfactory comparison between the lives of the Fellows, and those of the general population as shown in the accepted life tables, I have calculated, from the known ages of the Fellows at election, and the known dates of the deaths that have occurred among them, the average age of the Fellows remaining alive in each year. From these ages I have computed, from Dr. Farr's tables, the probable number of Fellows that would survive from year to year, assuming the initial number to be 15.

From Table III., above referred to, has been ascertained the number of Fellows surviving in each successive year after election, and thence has been obtained the average number surviving from an initial number 15.

The results of these computations will be found in Table IV.

The second column in this table shows the number of lives dealt with for each year after election. The first entry, 645, is the total number of Fellows elected in the whole 43 years. The next column to the right gives their aggregate ages, and the next their average age, 44·9, in their first year. Following the same line to the right, we find the average number of Fellows elected, and in their first year.

Passing to the second line of the table, 619, immediately below 645, is the total number of Fellows remaining in their second year from the elections of 42 years; this is succeeded, in the columns to the right, by their aggregate ages in their second year and their average age, and the average number in their second year, out of 15, the average number elected.

The third line gives the same data for the third year of Fellowship, and so on throughout, the last line but one showing that in their 42nd year there remained 6 Fellows from the elections of 2 years, with an aggregate age of 444 years, and an average age of 74·0, the average number surviving in their 42nd year, out of the 15 elected, being 3.

The sixth column of the table gives the successive sums of the numbers in the fifth column, and therefore indicates the aggregate number of Fellows that will, on the average, be surviving in each successive year of Fellowship, the number elected in each year being always supposed to be 15.

It will be seen that the total for the 43rd year is 397·0, whereas the actual number surviving, shown in column XI., is 401. This difference is of course due to the number 397 representing what the result would be if the average rates of election and decrease prevailed, instead of the actual rates for the separate years; and it is probably sufficiently accounted for by the fact, already pointed out, of the gradually increasing age at election in the later years, which will lead to the lives in the earlier years of the series being somewhat better than the average. Column XI. shows the *actual* results for successive years corresponding to the average results given in column VI. The differences will be seen to be somewhat irregular, but nowhere to be of importance.

Column VII. gives the aggregate ages of the numbers surviving in successive years, as shown in column V., and from it is deduced the average age of the whole number of Fellows shown in column VI., 397, which is seen to be 57·7 years, a result differing slightly from that obtained from the actual ages of the Fellows surviving in 1891, which was shown to be 58·4. The cause of this difference has already been indicated.

Columns VIII. and IX. supply the results that would be obtained by applying to an initial number of 15, the rates of mortality in Dr. Farr's tables, for the ages in successive years given in column IV. Column X. contains the ratio of column VI. to column IX., and indicates that throughout the whole period of 43 years the actual results are somewhat better than the tabular results, or that the lives of the Fellows are better than the ordinary lives, and that this advantage leads in the 43rd year to the actual number of survivors being rather more than 5 per cent. in excess of that which would be given by the life tables, or of about 20 on a total of 400.

An examination of this table will show that, with the exception of the last six or eight years, in which the number of lives dealt with at last becomes very small, the figures indicate a very regular and consistent progression, and it will practically be quite safe to assume that the series in column VI. may be extended on the basis of the ordinary life tables, subject to the addition of 5 per cent. on the total amounts obtained from these last.

Hence it will be found that in 10 years after 1891 the aggregate number of Fellows is not at all likely to be increased by more than 15, that the final result may be as little as 410, but is not likely to be more than 420, or at the outside 425.

In an earlier part of this paper, I mentioned that the rate of decrease of the Ordinary Fellows elected before 1848 did not appear to differ materially from that which has prevailed subsequently.

Taking the number of Ordinary Fellows elected before 1848, and then alive, at 718, it will be found that in 12 years (1860) the number was reduced to 422, which is about 60 per cent. of the original number; after 24 years (1872) the number fell to 206, which is about 30 per cent. of the original; and in 36 years (1884) there remained only 65, which is about 9 per cent. of the first number.

Assuming that the average age of the 718 Fellows elected before 1848, and then alive, was not materially different from (58) the average age of the Fellows elected after 1848 and alive in 1891, when it has probably become nearly stationary, it may be inferred that the lapses among a body of Fellows of that age will correspond to the lapses among the Fellows alive in 1848. Now, from Table IV. it will be seen that of the Fellows elected after 1848, the average age in their 17th year was 58·3 years, which is almost exactly the average age of the whole body. Further, it is shown that of the supposed original 15 there remained 10·9 in the 17th year of the age above mentioned, 58·3. This number was reduced in 12 years to 6·7, which is nearly 60 per cent. of the number in the 17th year, and again falls after 12 years more to 3·7, which is not very different from 30 per cent. of the starting number, and after 12 years more the number will be seen to be likely to be less than 1·0, which again will not differ materially from 9 per cent. of the original 10·9. These proportions, it will have been observed, are those above shown to hold in the case of the Fellows elected before 1848.

On the whole, it seems to be established that the present restriction to 15 of the number of Ordinary Fellows elected in any year will lead to an eventual maximum number not exceeding 420; and that the ultimate increase of the total strength of the Society, for each additional Fellow elected in excess of 15 may be taken at 28, so that an increase to 18 of the annual number of Ordinary Fellows elected would lead to an ultimate total of 500 such Fellows.

THE ERUPTIONS OF VULCANO (AUGUST 3, 1888, *TO MARCH* 22, 1890).[1]

THERE are some 180 (nominally 212) pages and 11 plates. Of these latter 4 are reproductions of Silvestri's beautiful whole-plate photographs [one of Vulcano at rest (with Vulcanello), and the other three instantaneous views of the volcano in eruption]. A fifth reproduces, half-size, two of Dr. Johnston-Lavis's instantaneous views of eruptions taken from the crater's edge.[2] Two other plates give 14 excellent photographs of the "bombs," and of the rest two are sketches of Stromboli crater, one petrographical, and the last the map of Vulcano (1/50,000).

---

[1] "Le Eruzione dell' Isola di Vulcano, incominciate il 3 agosto, 1888, e terminate il 22 Marzo, 1890: Relazione scientifica della Commissione incaricata degli studi dal R. Governo," *Annali dell' Ufficio Centrale di Meteorologica e Geodinamica*, Parte 4, vol. x., 1888 (Rome, 1891).

The Commission was originally as follows:—President, Prof. O. Silvestri (Catania), Prof. G. Mercalli (Milan), Prof. Grablovitz (Seismological Observatory, Ischia), and as engineer, V. Clerici (Messina), with A. Cerati, Prof. Ponte, and A. Silvestri, as assistants.

As is known, Prof. Silvestri died before the publication of the Report, but not till some months after the end of the eruptions, on which he had elsewhere published various papers. The Commission must thus have had full time to profit by his experience both in the field and afterwards, and his name appears as author or joint author of a number of sections. After Silvestri's death, Prof. Mercalli, the largest contributor to this Report, took his place, and brought the work to its completion.

[2] For others by Dr. Lavis and Silvestri, see "South Italian Volcanoes."

A table of contents may be found at the end.

Appended to the various sections are the names of the authors responsible. The 180 pages of text necessarily vary in character. Thus, 50 pages are devoted to an almost daily record of the state of the volcano during the twenty months of the eruption. For not a few days we have a record of the times and degree of violence of all the explosions which (February 12 and 14, 1889) might number more than 100 between 10 a.m. and 6 p.m. On the other hand, we find between pp. 207 and 210, a *résumé* of the chief facts observed, and the conclusions to which they point.

There are 20 pages (9–29) on the topography and geology of the island of Vulcano. Details are given as to the rocks collected at various localities, and the conclusion (expressed with some reserve) as to the history of the island, is very similar to the view stated (Proc. Geol. Assoc., vol. xi. pp. 395-96, 1890) by Dr. Johnston-Lavis.

The author (Mercalli) only recognizes one crater (with lavas of andesitic and basaltic type) in the "Piano" district, which forms the southern half of the island. The Serro di Capo and Monte Lentia represent the western part of a second old (north-west) crater of more "acid" type, which may have had its centre almost coincident with that of the present active cone, and which, judging by the weathering of the rocks, may be older than the Piano crater. The author notices that the straight north and south line, drawn from *Vulcanello* through the *hot springs* by the "Faraglioni" and the two overlapping "*Forgia Vecchia*"-*s* (on the north flank of Vulcano) to the present crater (or "*Fossa di Vulcano*"), if continued, strikes *Monte Saraceno* (a lateral cone on the north-west edge of the Piano crater). It is then pointed out that, assuming Monte Saraceno to be situated over a continuation of the crack which most probably runs from Vulcano to Vulcanello, and assuming the present eruptive centre to coincide with that of the old north-west crater, that then the present "Fossa di Vulcano" is situated on the point of meeting of two cracks, viz. a north to south one from Vulcanello to Monte Saraceno, and a north-west to south-east one joining the more ancient craters. The present crater would then be situated over a weak point. Whether or no Monte Saraceno be situated over a crack extending south from Vulcano rather than over some other, there is nothing at any rate in the above against the view expressed in Prof. Judd's "Volcanoes" (see Fig. 81), according to which there is one main crack beneath the island of Vulcano, the crack from Vulcano to Vulcanello being but a continuation of that on which the more ancient craters lie. As to the number of craters more ancient than the main modern cone, it will be seen that the Report takes a view intermediate between that of Scrope ["Volcanos," 2nd edit., p. 192, Fig. 47] and that of Judd ["Volcanoes," p. 196, and Figs. 77 and 85].

The twenty pages (30–50) devoted to the records of previous eruptions are naturally full of interest. A number of quotations from older writers are given. The conclusion is that the eruptions of Vulcano in the historic period have been on the whole very similar.

As interesting dates may be noticed:—475 B.C., Vulcano in activity (Thucydides); 183 B.C., Vulcanello formed; about 1550 A.D., strait between Vulcanello and Vulcano filled up by eruption of the latter; 1727, Forgia Vecchia (on north slope of Vulcano) in eruption (D'Orville); 1771, "Pietre Cotte" obsidian stream (on north flank of Vulcano) poured out; 1878, Fumaroles still visible on Vulcanello.[1]

From p. 53 to p. 174 is devoted to (1) detailed record of the eruptions, as to which a valuable *résumé* is given, pp. 112–14; (2) seismological and various other physical observations; and (3) the description of the erupted products.

The following epitome is based on that given by Silvestri, pp. 207–208:—

(*a*) The recent activity of Vulcano lasted 20 months, viz. August 3, 1888, to March 22, 1890 (with final explosions, May 17), the most violent explosions (p. 113) occurring on August 4, 1888, December 26, 1889, and March 15, 1890. There had previously been a period of repose (1832–72), followed by minor premonitory eruptions in 1873–7–8–9 and 1886.

(*b*) Just as we have the "*Plinian*" or "*Vesuvian*" eruptions of Vesuvius accompanied by violent outbursts of "ashes" and welling out of lava, and the incessant, milder "*Strombolian*" type of eruption, so we may distinguish a "*Vulcanian*" type (pp. 58–59). Characteristic of this are—

(i.) Intermittent explosions with discharge of bombs, ash, dust, and vapours. Each of these explosions resembles the first outburst of "Plinian" ("Vesuvian") eruptions (p. 112).
(ii.) The absence of lava streams.
(iii.) The absence of noteworthy earthquake shocks.

(*c*) The more violent of the explosions burst out suddenly, discharging clouds of vapour, with dust lapilli, and more or fewer bombs and fragments of compact lava, and such an explosion was then followed at short intervals by feebler ones, which merely discharged the smaller materials, or vapours only.

(*d*) The more violent explosions were generally separated by longish intervals, either of absolute repose, or with insignificant explosions; and, on the other hand, when eruptions took place every few minutes, they were generally feeble.

(*e*) (p. 113, 70) Observations of atmospheric pressure extending over a day, or short period of time, show no relation to the frequency or degree of violence of the explosions. But viewing the 20 months of the eruption as a whole, it is found that Vulcano enjoyed comparative repose during periods of high atmospheric pressure, or of small change, and was most active during periods of change from fair to stormy weather, with marked fall of barometer.

(*f*) Though during the 20 months of the eruption there were altogether a good many earthquakes recorded either by the seismoscope, or by some of the inhabitants (pp. 134–37), still these were but slight, and, as stated, formed no feature of the eruption, being very rare compared with the explosions.

It was found (pp. 125–28) that for making observations of the shocks or tremors accompanying the explosive eruptions, even close to the foot of Vulcano, seismoscopes were as a rule not sensitive enough. On the other hand, owing to the frequency of the explosions, a tromometer was never quiet. The simplest method is often the best, and recourse was had to pools of mercury (at once sensitive and stable). With the aid of a reflector it was then easy to keep an eye at once on the reflection of some object in the mercury, and on the lip of the crater, and so observe the time relation between the tremors and the explosive outbursts.

Observations made near the base of Vulcano showed that each eruption was preceded by a short tremor (apparently the result of a deep-seated explosion), followed after a short interval of calm, of from a few seconds to three-quarters of a minute, by another, the result, apparently, of the superficial explosion that made a vent for the vaporous and solid ejecta. The interval was shorter in the case of the more violent explosions.

(*g*) In the first three days of the eruption (pp. 54 and 152–58), August 3–5, 1888, the ejecta consisted mainly of a variety of old materials blocking the neck of the volcano. These, much of which was more or less altered by solfataric action, were discharged in pieces of all sizes from fine dust to large masses.[1]

(*h*) After an interval of thirteen days, the second main period of the eruption set in. The older materials soon became almost entirely replaced by newly elaborated matter in the form of dust, lapilli, lighter or heavier "bread-crust" bombs,[2] and masses of compacter lava. These, as opposed to the matter discharged during the first three days, were all, except for inclusions of older rocks, of essentially similar mineralogical and chemical constitution (of andesitic type (p. 165), with 62–67 per cent. of silica, the percentage of which might be greater in the centre than in the crust of the same bomb). The larger masses on leaving the crater had a high initial temperature, and were plastic, taking rounded, elongated, or flattened forms, and on reaching the ground melted various metallic wires—silver (1000° C.), and copper (perhaps 1200°, but, as we are cautioned, the copper might oxidize and then fuse lower).

From the preceding, Silvestri draws the following conclusions:—

(Excluding the ejecta of the first three days) The high temperature and plasticity, with the presence of inclusions of older rocks, and the uniform composition of the ejecta, point to their being derived from a molten magma of recent elaboration. Of this, all things considered, there was probably a vast reservoir at a depth probably far below the bottom of the adjacent sea (which is 670 metres on the east, and 500 metres on the west). At intervals the steam included in this molten lava would acquire sufficient force to burst forth, producing the premonitory tremor (see (*f*) above, and pp. 125–28); and though it is not very clearly stated, I gather that the interval of calm between the first and second tremors is considered to have been occupied by the escape of such steam into the space between the surface of the deep-seated lava and the crater floor, till it acquired sufficient pressure to force an exit through the mouth of the crater (which became plugged by the fall of ejecta after each eruption). Then the visible explosion would take place, accompanied by the second tremor.

---

[1] Dr. Lavis found these practically extinct in 1887 (see NATURE, vol. xxxviii. p. 13).

[1] The Report describes these as not so hot as the later ejecta. However, from Mr. Narlian's graphic account (*Times*, September 13, 1888, and Brit. Assoc. Report, 1888, p. 665) it would seem that, at the first outburst, some of the ejecta fell red-hot, so as to set hedges, &c., on fire.

[2] Dr. Lavis, in NATURE, vol. xxxix. p. 110.

The "bread-crust" bombs (with pumiceous interior and cracked subvitreous crust) are said to commonly contain inclusions of older rock, and it is suggested (pp. 163 and 209) that the frothing up of the interior is *in part* due to these, for, says he, fragments of rock falling into a superhydrated molten lava may not improbably act as centres of ebullition, just as solids (in proportion to their extent of surface) cause rapid disengagement of gas when dropped into "soda"—or other aërated—waters.

The compact fragments and masses sometimes ejected (pp. 120, 160, and 209), notably in the last eruption, might be explained as pieces of the shells of domelike bubbles which had partly consolidated below the volcano, or as derived from less hydrated parts of the magma.

If there was this huge lake of lava and so much steam, why did not the lava appear at the surface? Silvestri points out that the rise of the lava will depend on the proportion of the compressed steam to the mass of the lava that contains it, and on the resistance offered to its escape. If the exit of the steam is blocked by lava, we may have all the phenomena of a "Plinian" ("Vesuvian") eruption. On the other hand, in 1888 Etna had eruptions of vapours only, and we get all stages between these two. In the case of a large space partly filled with lava at a great depth below the surface, the conditions might well be such that the steam would escape long before the lava overflowed.

Among other points dealt with in the Report may be noticed:—Pp. 143–45, the breaking three times during this eruptive period of the submarine cable between Lipari and Milazzo in Sicily. The first and third breaks were near the same spot, and near a place where the sea was seen to "boil," with pumice rising to the surface.

On p. 147 observations are recorded which support the view that the electric discharges accompanying eruptions depend principally on the friction of much dust and fine ejecta. Violent explosions discharging large masses, if unaccompanied by such finer matter, might be without the electric phenomena (p. 146).

There are ten pages on the state of Stromboli during the eruption of Vulcano, from which there appears to have been no relation between the two. Nor do the "secondary phenomena" (the hot springs and fumaroles) in these islands appear to have been markedly affected. Some of the fumaroles increased and some decreased in vigour, and some showed no change.

From what has been said as to the slight seismic effects, we are prepared to hear that no change in the level of the land was produced. In this connection there is a chapter on the tides, which have an amplitude at Lipari of about 30 cm.

On p. 120 are given four sections, in three, of the crater of Vulcano before, during, and after the eruption, from which it is seen that the crater has been much filled up.

On November 18, 1891, the writer found the crater still in the quiet solfatara condition, so that one could descend into it. The higher slopes were covered with white, and the lower, where the fumaroles were more marked, with yellow and red crystalline deposits. A little water lay at the bottom. The deepest part was a funnel-like depression, a little to the north of the middle, somewhat as shown in Mercalli's figure for April 1890. This marked the last eruptive vent.

In conclusion, then, the Report contains a great mass of facts, and in addition generalization and theory, which, as often based on long experience, are also welcome; and the Commission is to be congratulated.

G. W. BUTLER.

SOCIETIES AND ACADEMIES.

LONDON.

Anthropological Institute, May 10.—Dr. Edward B. Tylor, F.R.S., President, in the chair.—The election of the Duke of Devonshire and Dr. H. Colley March was announced.—Mrs. Bishop (Miss Isabella Bird) read a paper on the Ainos of Japan, amongst whom she had spent some time in a village near Volcano Bay. It is doubtful whether the Ainos were the aboriginal inhabitants of Japan; they say themselves that they conquered and exterminated an earlier race who dwelt in caves. The men are strongly built and muscular, and their stature varies from about 5 feet 4 inches to 5 feet 6 inches. The extreme hairiness ascribed to the Ainos applies only to the mountain tribes, and to the men only amongst them; the women, and the men of the coast tribes, not being more hairy than many people of other races. The houses are rectangular and built of wood; they are all constructed on the same plan, and have a large window at the east end opposite the door, and two smaller ones in the south side, below which is the shelf on which the boys of the family sleep; the girls occupy a similar shelf on the north side of the room, and during the night the sleeping-places are screened off by mats. The women are remarkable for their modesty, and the men are exceedingly gentle, obliging, and hospitable. They are a religious people, and offer copious libations of "saki" on the slightest provocation. The race is dying out, and will no doubt be quite extinct in the course of a few generations.

PARIS.

Academy of Sciences, May 24.—M. d'Abbadie in the chair.—Heats of combustion and formation of alcohol and of formic and acetic acids, by MM. Berthelot and Matignon.

$$\mathrm{C_2(diamond) + H_6 + O = C_2H_6O}\left\{\begin{array}{lr} & \text{Cal.}\\ \text{liquid} \ldots & +\,69{\cdot}9\\ \text{gas} \quad \ldots & +\,59{\cdot}8\\ \text{solution} & +\,72{\cdot}4\end{array}\right.$$

Heat of combustion of liquid alcohol at constant pressure = 324·5 cal.

$$\mathrm{C\ (diamond) + H_2 + O_2 = CH_2O_2}\left\{\begin{array}{lr} & \text{Cal.}\\ \text{solid} \quad \ldots & +\,103{\cdot}3\\ \text{liquid} \quad \ldots & +\,100{\cdot}8\\ \text{gas at } 200^\circ & +\,90{\cdot}0\end{array}\right.$$

Heat of combustion of liquid formic acid at constant pressure = 62·5 cal.

$$\mathrm{C_2(diamond) + H_4 + O_2 = C_2H_4O_2}\left\{\begin{array}{lr} & \text{Cal.}\\ \text{solid} \quad \ldots & +\,119{\cdot}7\\ \text{liquid} \quad \ldots & +\,117{\cdot}2\\ \text{gas at } 250^\circ & +\,107{\cdot}1\end{array}\right.$$

Heat of combustion of liquid acetic acid at constant pressure = 209·4 cal.—Some facts in the chemical history of nickel, by M. P. Schützenberger.—Degradation products of the tissues, particularly of the muscles, separated from the living being: analytical methods, by MM. Armand Gautier and L. Renou.—On a natural ice-cave at Creux-Percé (Gold Coast), by M. E. A. Martel.

Berlin.

Meteorological Society, May 3.—Prof. von Bezold, President, in the chair.—Dr. Schwalbe gave an account of observations on the extent and spread of anomalies of temperature in Germany based on synoptic weather-charts. He showed that the weather-types introduced by Teisserenc de Bort hold good for Germany, especially in winter, and that, as a result of the varying distribution of barometric pressure, they are the cause of very marked differences of temperature between the north and south, the east and west. These types are less frequently observed in summer, although both then and in the spring certain very marked distributions of pressure exist.—Prof. Spörer spoke on the recent magnetic storm of April 25, for which, as also for the great storms of February 13 and 14, he had been unable to discover any corresponding phenomena in the sun-spots at the same dates.

DIARY OF SOCIETIES.

A PROFESSORIAL UNIVERSITY OF LONDON.

THE recent history of the London University question affords decisive proof that the new University, which is to be the outcome of the labours of the Royal Commission now sitting, must be much more than a merely exclusive or merely local institution. Of the two main objects of a University in any English sense of the expression—the promotion of the higher education, and the advancement of learning—both must be equally subserved; and neither will be attained if the new University be established on other than the broadest possible basis, or if its development be controlled and hindered by rivalries that could not but become of an ignoble character. In the course of discussion it has been made abundantly clear that a duplication of Universities in London would be a misfortune of the first magnitude, dividing resources and diverting energies into channels that would lead to many undesirable results. It is equally clear that a University, consisting of a federation of local educational institutions existing within the same narrow area, would be wanting both in unity and force: its government would tend to become a succession of compromises effected between the interests, almost wholly of a financial nature, of its constituent Colleges. It may, then, be taken as a conclusion accepted by the great majority of those who have given special attention to the subject that there should be one University, and one only, in London, and that it should not be of a federal character. To this position it is a simple corollary that the government of the proposed University should be vested mainly in a professorial body. Much the most important work of the University would be the enactment of curricula and syllabuses and the control of teaching and examination—work that can only be efficiently performed by those specially familiar with the subjects taught. With the Professors a proper number of Crown nominees should be associated to act as moderators and as representatives of general educational policy, as well as to guard the interests and assure the continued confidence of the public. With the mode of creation and with the functions of the usual Faculties, and with the details of examinational systems, we need not at present concern ourselves. In fact, the less the new University is fettered by any Charter or Act the better, and it would be a misfortune were the precedent followed of the complicated and minutely detailed Charter recently rejected by the Convocation of the London University. On that occasion, it must be admitted, Convocation made good use of its veto, but its continued possession of such a power would, we think, be a source of disquiet and danger, without any corresponding advantage to Convocation itself, or the University—especially a professorial University—or indeed to the public. A much more useful provision would be the grant of a power of appeal to some such Committee of the Privy Council as that by whose aid the Scotch Universities are enabled to settle their differences.

The possibility of any such University as we have indicated above ever coming into existence—and for a University of any other kind it is scarcely worth while to exert oneself—depends largely on the good will of the existing Colleges. They must follow the capital example set by Bedford College, and signify their willingness to be merged in and become part of a true London University with such reservations in respect of particular portions of their collegiate work as may be necessary. As far as the professorial staffs of these Colleges are concerned, there can be little doubt but that they would hail such an event; but it is possible that the governing bodies may take a different view. And with regard to the Medical Schools, the reservations touching their purely professional work, must, from the nature of the case, be extensive.

Though, for the moment, the question of a new University is chiefly interesting from the point of view of science and medicine, what for the sake of brevity may be termed the arts aspect of the question must not be neglected. There are very few science students who do not follow—and follow of necessity—special courses of instruction in fairly equipped laboratories; but the arts student is less constrained in his mode and course of study—he has, indeed, in London less opportunity of benefiting by adequate instruction in the subjects of his studies. The stimulus to every form of education that the new University may be expected to give will supply this deficiency; but meanwhile, and probably to a greater or less extent always, the case of the "private student' in arts will have to be considered. We shall not enter upon it here. Our object in mentioning the case of the arts student is rather to show that the interests of the two great divisions of human knowledge are at one in the matter of the proposed University. It may be added that the "private student" difficulty, so far as it exists, should be left to be dealt with by the new University. It is limited in character, though extensive in scope, and is very far indeed from being insurmountable.

To resume. We are entirely in favour of a single non-exclusive London University, mainly, or at least adequately, of a professorial character—which by no means necessarily involves the extreme teacher-examiner system—controlling both teaching and examination, and being or becoming, by absorption or otherwise, homogeneous in interest, and in the highest degree authoritative in function. All these features are entirely novel; they are not, we believe, possessed by any British University. And herein lies the practical difficulty now to be confronted. The present opportunity for creating such a University is not likely to recur, at all events for some generations to come. What is to be done to make the best of it? The Royal Commission is fully aware of the greatness of the task committed to it, and has entered upon its labours in no niggard, narrow, or unappreciative spirit. But the Commission must be aided by educational opinion clearly thought out and firmly expressed. It must have the support of the London University, of the great Colleges, of the Medical Schools, and of the professorial body in London, who should be aided by the sympathy of their brethren in the provinces—a sympathy, there is good reason to believe, that will not be wanting. Such professorial opinion will include that of the staffs of the Colleges and Schools, and of those members at least of the Senate and Convocation of the University of London who are or have been engaged in professorial work. So powerful a body of opinion cannot but exert a great—indeed, a decisive—influence upon what may be termed the lay elements of the governing bodies, whom we can only reach through their professorial colleagues.

It is difficult to see how the arguments of eminent specialists in support of the general arguments called forth by the occasion can be rejected, when once the novelty of their proposals has been got over. Convocation, with an appeal to the Privy Council, will have a far more usable and useful power than is inherent in the bare obstructiveness or quasi-terrorism of the veto. The Senate in Burlington Gardens will scarcely refuse to complete the University character of the great institution it governs, and perfect its educational machinery, by placing the responsible direction of the higher education of all its students, without exception or distinction, in the hands of the most eminent representatives of those who have made such education the business of their lives. The Medical Schools will only give up the teaching they are least adapted to furnish, and in lieu of being scattered entities, will become integral portions of a great whole. The private arts student will retain every advantage and privilege he possesses, and cannot but gain by working under syllabuses prepared by past masters in the art of teaching.

Perhaps the best procedure to be adopted by the Professoriate, with whom the initiation of any active propaganda must lie, will be to lay their views before the governing bodies by deputation, and before the Commission by the individual testimony of such among them as may be invited to give evidence on the question. Here a word of caution may not be out of place. Details of a ministerial nature should be avoided as much as possible, for until the main lines of any scheme are settled, it is difficult to say what details are possible or necessary. It is still more important to shun any approach to doctrinairism, the besetting vice of professordom, and treat every principle as modifiable by the circumstances of history, national habit, and environment.

On the financial aspect of the question we can say little. The establishment of a new University will cost money, but no great sum will be needed to start with. The University will, of course, be independent, and the necessary expenses will be defrayed in part by an annual Government grant. Among other sources of income, the funds at the disposal of the County Council may perhaps be counted, and with a view to such assistance it might be found advisable that the University should have a commercial and technical, as well as a purely academical side.

But for the moment, what is of most importance is, we repeat, that the London Professoriate should organize itself, formulate its principles of action in the sense above indicated, and use its influence, publicly and privately, to procure their acceptance as far as circumstances may show to be possible.

INDIAN BOTANY.

Annals of the Royal Botanic Garden, Calcutta. Vol. III. (1) The Species of Pedicularis of the Indian Empire and its Frontiers, by D. Prain, M.B., F.R.S.E., Curator of the Herbarium. (2) The Magnoliaceæ of British India, by G. King, M.B., LL.D., F.R.S., C.I.E., Superintendent of the Garden. (3) The Genus Gomphostemma, by D. Prain. (4) The Species of Myristica of British. India, by G. King. 4to, pp. 350, tt. 174. (Calcutta: Printed at the Bengal Secretariat Press, 1891.)

THE two previous volumes of this publication are devoted entirely to the illustration and description of the arboreous element in the Indian Flora, and the letter-press is solely the work of Dr. King. Volume I. deals with the difficult genus *Ficus*, illustrated by 232 plates; and the second volume treats of the almost equally difficult genus *Quercus* and the allied *Castanopsis*, as well as the genus *Artocarpus*, of which seventeen species are described and figured. As may be seen from the list of papers given above, the work in the present volume is partly by Dr. King, and partly by his Curator, Dr. Prain; the former continuing his valuable labours on the trees of India, whilst Dr. Prain has taken up two herbaceous genera. A critical review of this ponderous volume would require more space than could be given to it in the pages of NATURE, and a much deeper knowledge of the subjects than the writer possesses; but it is not a difficult task to give an idea of the nature and quality of the series of monographs it contains. At the outset one is disposed to find fault with the bulk and fourteen pounds weight of this book, because it is really fatiguing to handle, and smaller volumes are in every way more desirable. Fortunately, the present volume may be conveniently bound in three nearly equal parts, as each monograph has its separate title-page and index. Indeed, it might be preferable to bind each of the four monographs separately.

The present volume, it will be perceived, is partly devoted to utilitarian botany, which will be welcome to the forestry department, as well as to botanists generally, and partly to botany of a kind that appeals more especially to the biologist. Dr. Prain's elaborate and painstaking monograph of the genus *Pedicularis* belongs to the latter category, and may be recommended for study to the young aspirant for honours in the same direction as a model of thoroughness, so far as external morphology goes. To persons acquainted only with our two native species of *Pedicularis*, the wide range of modification exhibited in the forms of the corolla is surprising, and reminds one of Prof. Huxley's remark that the genus *Gentiana*, as generally circumscribed, presents nearly as much variation in the shape of the corolla as all the genera of the Gentianaceæ combined. This polymorphism is sufficiently illustrated in the comparatively recent monograph of the whole genus *Pedicularis* by the late Mr. Maximowicz. He figures the flowers of all the species known to him, whilst Dr. Prain figures the plants, or portions of the plants, of all the Indian species, as well as their flowers. Great as is the variety, however, in the size and shape of the corolla in *Pedicularis*, it would be wrong to say that it is nearly as great as in the whole order of the Scrophularineæ. The two principal kinds of variation are the length and the relative diameter of the tubular portion, and the shape of the lips, especially of the upper one, of which there are many curious and even fantastic modifications. Maximowicz's monograph of the whole genus (which is dispersed all round the northern hemisphere, and perhaps extends just over the equator in the Andes) includes about 250 species, and a few have been discovered in India and China since. Prain's monograph of the Indian species contains nearly double the number described in the "Flora of British India" in 1884. The systematic part is preceded by an elaborate and masterly essay on the distribution and descent of the species, illustrated by diagrams and a map. The latter might certainly, with a little extra work, have been made clearer. Dr. Prain divides the genus primarily into three groups—namely, *Longirostres*, *Aduncæ*, and *Erostres*—based on the modifications of the upper lip of the corolla; and the names are sufficiently descriptive to indicate their application. Each of these groups contains both opposite (or verticillate) and alternate leaved species, and is subdivided into a number of sections. So far as we have tried the keys to the sections and species we have found them work admirably, and the descriptions are evidently very carefully written; but twelve to eighteen lines of description in the ablative absolute without a stop or any variation in type is bewildering, and an innovation that is to be deprecated. Dr. Prain himself appears to have realized this, for in his account of *Gomphostemma* his descriptions are shorter and punctuated, with the names of the various organs in italics.

Dr. King's monographs of the Magnoliaceæ and the genus *Myristica* are written entirely in English, perhaps with advantage, because Latin descriptions are not so easily understood as English by many persons interested in trees. Including the suborder Schizandreæ, the number of Indian Magnoliaceæ described and figured is forty-five, referred to eight genera.

Passing on to his monograph of the species of *Myristica* of British India, we find that he distinguishes sixty-eight, illustrated by sixty-nine plates. By British India, Dr. King understands political British India, including the Nicobar and Andaman Islands, and the territories of the Straits Settlements. Dr. King follows Bentham and Hooker, and others, in referring all the nutmegs to the one genus *Myristica*, and, as thus limited, it is represented in nearly all tropical countries. Ten years ago, less than a hundred species were described, but Dr. Warburg, who is at present at Kew engaged on a monograph of the order, estimates the number now in herbaria at about 200. This great augmentation is almost wholly from discoveries in the Malayan Peninsula and Archipelago, New Guinea, and Eastern Polynesia. Dr. King abstains from any attempt to trace the geographical distribution of the species, on the ground that he believes many yet remained to be discovered. But on running through his work we find that about fifty-four of his sixty-eight species are from the Malayan region, eight from the Deccan and Ceylon, and about six from the Assam and Chittagong region, only two apparently being found as far westward as Sikkim, in North India. Most of the new species are from Perak, a country exceedingly rich in endemic trees. Beyond the distribution indicated, there is one species in North Australia, and four each in Madagascar and Tropical Africa, and perhaps about forty or fifty in America, extending from South Brazil through the West Indies and Venezuela to Central America and South Mexico. The author is careful to explain that he does not regard the present effort as anything approaching finality, and anyone acquainted with the genus will understand the difficulties encountered in working from herbarium specimens alone. With one interesting exception (*Myristica canarioides*, King) the species are diœcious, and female flowers are much rarer than males; and the fruit, which affords good characters in a fresh condition, is often wanting, or not in a good state for description. But if Dr. King's work is necessarily incomplete, it supplies the very best materials for the foundation of a more exact knowledge. The figures, although possessing no great artistic merit, are faithful portraits of authentic specimens of the several species, and, combined with the very full descriptions, are sufficient to enable botanists to determine most of the species. On the other hand, the fine work in the analyses of the flowers is indistinctly reproduced in some of the plates, apparently in consequence of their having been drawn on too small a scale. The flowers, it may be added, of many species, are exceedingly small, of some not more than a twentieth of an inch in diameter. But I must draw this notice to a close with the remark that this volume is a monument to the skill and industry of Dr. King and his colleague, and a credit to the native lithographers and printers. One only marvels how the authors, with their multifarious duties, accomplish so much in a tropical climate.

W. BOTTING HEMSLEY.

MATHEMATICAL RECREATIONS AND PROBLEMS.

Mathematical Recreations and Problems of Past and Present Times. By W. W. Rouse Ball. (London: Macmillan and Co., 1892.)

THE idea of writing some such account as that before us must have been present to Mr. Ball's mind when he was collecting the material which he has so skilfully worked up into his "History of Mathematics." We think this because the extent of ground covered by these "Recreations" is commensurate with that of the "History," and many bits of ore which would not suit the earlier work find a fitting niche in this. Howsoever the case may be, we are sure that non-mathematical, as well as mathematical, readers will derive amusement, and, we venture to think, profit withal, from a perusal of it. The author forewarns possible readers that "the conclusions are of no practical use, and most of the results are not new." This is plain language, but, lest the warning should be too effectual, he adds, "At the same time I think I may assert that many of the questions—particularly those in the latter half of the book—are interesting, not a few are associated with the names of distinguished mathematicians, while hitherto several of the memoirs quoted have not been easily accessible to English readers." We have thus stated the author's *pros* and *cons*, and remark that he has gone very exhaustively over the ground, and has left us little opportunity of adding to or correcting what he has thus reproduced from his note-books.

There are two sources to which every writer on the subject of the earlier part must apply, viz. the "Problèmes plaisans et délectables," by C. G. Bachet, Sieur de Meziriac, and Ozanam's "Récréations mathématiques et physiques." These Mr. Ball carefully discusses as to editions and their respective merits.

The work before us is divided into two parts: mathematical recreations and mathematical problems and speculations. The former consists of seven chapters. In the first chapter are collected together numerous problems with numbers, watches, and cards. Some of these last are interesting to the mathematician, and have been discussed in the *Messenger of Mathematics* and the "Reprint from the *Educational Times*." The Middle Ages furnish some curious questions, and an antique problem in *decimation* is associated with the name of Josephus, but these are well-known instances. Bachet's weights problem calls for mention. It finds a place in the author's algebra; the omissions in Bachet's argument, Mr. Ball notes, have been supplied by Major MacMahon (see NATURE, vol. xlii. pp. 113, 114). Mersenne's numbers have been treated recently at some length by Mr. Ball in the *Messenger of Mathematics* (vol. xxi. pp. 34–40); in this account it is stated that $2^{61} - 1 = 2\,305\,843\,009\,213\,693\,951$ is the biggest known prime. Fermat claims some space (cf. NATURE, vol. xviii. pp. 104, 344). Of his so-called *last theorem* (no integral values of x, y, z, can be found to satisfy the equation $x^n + y^n = z^n$, if n is an integer greater than 2) we read:—

> "This proposition has acquired extraordinary celebrity from the fact that no general demonstration of it has been given, but there is no reason to doubt that it is true."

It is fitting that we should give Mr. Ball's grounds for this belief.

> "Fermat was a mathematician of quite the first rank who had made a special study of the theory of numbers. That subject is in itself one of peculiar interest and elegance, but its conclusions have little practical importance, and since his time it has been discussed by only a few mathematicians, while even of them not many have made it their chief study. This is the explanation of the fact that it took more than a century before some of the simpler results which Fermat had enunciated were proved, and thus it is not surprising that a proof of the theorem which he succeeded in establishing only towards the close of his life should involve great difficulties."

Proofs have been given in the cases of $n = 3, 4, 5, 7, 14$ (cf. pp. 28, 29). Many subjects of interest take up the second chapter, as "Geometrical Fallacies" (every triangle is equilateral, and the whole is equal to a part: this latter we think we have seen in an article by De Morgan); curious "Proofs by Dissection" (cf. *Messenger of Mathematics*, vol. vi. p. 87), there is a printer's error (p. 35, l. 9 up) of $\tan^{-1}\frac{1}{40}$ in place of $\tan^{-1}\frac{1}{46}$; "Colouring Maps" (only four colours necessary to colour a map of a country, divided into districts, in such a way that no two contiguous districts shall be of the same colour), the literature of this problem is brought fully up to date; an account is given of the results of Cayley's "Contour and Slope Lines," and of Clerk Maxwell's "Hills and Dales." Then follow "Statical Games of Position" ("Three in a Row" and "Tesselation," both problems connected with the name of Sylvester); "Dynamical Games of Position" ("Shunting," "Ferry-boat Problems," and numerous counter, pawn, and solitaire problems), and a glance at "Paradromic Rings."

Chapter iii. treats of "Some Mechanical Questions," as "Perpetual Motion," the "Underhand Cut on a Tennis Ball" (*Messenger of Mathematics*, vol. vii.), the "Boomerang," and the "Flight of Birds" (NATURE, 1890–91). In chapter iv. we have a miscellaneous lot, the fifteen puzzle, Chinese rings, the fifteen school-girls problem, and such card problems as Gergonne's pile problem, the mouse-trap, and many others. Chapter v. discusses "Magic Squares," and chapters vi. and vii. are devoted to "Unicursal Problems." These are Euler's problem (more fully discussed by Listing, "Topologie," and Tait), mazes, geometrical trees, the Hamiltonian game, and the knight's path on a chess-board. All these matters are treated lucidly, and with sufficient detail for the ordinary reader, and for others there is ample store of references. There is no chance of catching Mr. Ball tripping in his use of books, and his ready access to mathematical journals can hardly be surpassed, so that we have not come upon any new facts. We may mention, however, in connection with the knight's path, that there is a short article, accompanied by diagrams, on the subject in the *Leisure Hour* (December 20, 1873), by H. Meyer, of the *Hannoverische Anzeiger*.

The second part, in its opening chapter, gives at some length an account of the three classical proplems, viz. the duplication of the cube, the trisection of an angle, and the quadrature of the circle. Chapter ix., on astrology, has many curious details relating to that science, and gives a facsimile of Cardan's drawing of the horoscope of Edward VI., with an abstract of Cardan's account. On the whole matter of the chapter Mr. Ball writes:—

> "Though the practice of astrology was connected so often with impudent quackery, yet one ought not to forget that nearly every physician and man of science in mediæval Europe was an astrologer. These observers did not consider that its rules were definitely established, and they laboriously collected much of the astronomical evidence that was to crush their art. Thus, though there never was a time when astrology was not practised by knaves, there was a period of intellectual development when it was accepted honestly as a difficult but real science."

De Morgan, it may be remembered, in the "Budget" (p. 278) says:—

> "If anything ever had a fair trial, it was astrology. The idea itself is natural enough. A human being, set down on this earth, without any tradition, would probably suspect that the heavenly bodies had something to do with the guidance of affairs."

"Hyperspace," which occupies chapter x., has a full bibliography (compiled by G. B. Halsted, *American Journal of Mathematics*, vols. i. and ii.), forms the subject of one of Mr. Hinton's interesting "Scientific Romances" (cf. NATURE, vol. xxxi. p. 431), and is connected with Dr. Abbott's "Flatland" (NATURE, vol. xxxi. p. 76). Mr

Ball has made all these the text for a clear account of our present knowledge of higher space. The two last chapters rapidly survey "Time and its Measurement" and "The Constitution of Matter."

Our analysis shows how great an extent of ground is covered by the "Mathematical Recreations," and when we add that the account is fully pervaded by the attractive charm Mr. Ball knows so well how to infuse into what many persons would look upon as a dry subject, we have said all we can to commend it to our readers. The book is most carefully printed (only three or four typographical errors have met our eye, and the figures on pp. 32 and 33 the student will recognize must be drawn incorrectly).

SOILS AND MANURES.

Soils and Manures. By John M. H. Munro, D.Sc. (Lond.) (London: Cassell, 1892.)

THE preface to this book informs us that "it is written for the use of young people in schools and colleges, and those numerous other readers who take an intelligent interest in the how and why of familiar facts and operations, yet have no special training in the language and methods of science."

We must admit that Dr. Munro has succeeded in his endeavour to write a book so simple that it may be put into the hands of a beginner with confidence that he will find few difficulties unexplained, and so trustworthy that the more advanced student may find it helpful and suggestive.

We are having a flood of small agricultural books just now, consequent upon the great movement for technical education in England, but we believe that this book will reach two classes of readers which the majority of other text-books do not seem to have affected. These two classes of readers are farmers and teachers in elementary schools. Too many of these books are written with the idea of preparing students for examination, and they may serve their purpose, but are not very likely to help forward the cause of technical education in agriculture to any considerable extent.

Such education has lately been much talked about, and written about also, and men of authority and experience have even gone so far as to say that the recent attempts to promote it have mostly been failures. But if the means employed have proved inadequate or unsuitable, it does not follow that technical education in agriculture is unnecessary, or that suitable means and methods of promoting it cannot be found.

To attempt to teach the principles of agriculture to men who have no knowledge of either elementary chemistry or botany can scarcely be expected to be generally successful, nor do we hear good accounts of lectures given to farmers by men whose agricultural experience has been mainly limited to the class-room and the laboratory, and who are apt to confound agricultural chemistry with agriculture itself. Yet there are very many earnest workers on the County Councils, who have the cause of agricultural education too much at heart to let a few failures and disappointments dishearten them, and, before very long, we feel sure that they will have more reason for congratulation than at present.

Meanwhile, we can welcome this book of Dr. Munro's and wish it the success it deserves, for not only does the author avoid errors himself but he corrects a few which some other writers of elementary text-books on agriculture have fallen into. Thus, on pp. 20 and 132, he removes the impression which many beginners get (from some "cram-books" we have seen) that silica in a soluble form is very essential as a plant-food, especially to cereals. Only those who are familiar with answers to examination papers in agriculture have any idea how frequently this mistake is made.

The first part of the book, comprising five chapters, will give the reader a very good account of soils, their formation and properties; also of plant-food in the soil, how it is increased, and how rendered available for the use of plants. Included in this first part are two chapters on "Improving the Land" and "Tillage Operations," from the pen of Prof. Wrightson. These fit in well with the rest of the work.

The second part deals with the subject of manures pretty exhaustively, the author giving many illustrations from the Rothamsted experiments. The last chapter, on "Special Manures," gives instructions for valuing artificial manures from the chemical analysis, and we feel sure that the matter dealt with in this chapter will be specially useful, and do at least a little to help the farmer from being defrauded by some few unscrupulous manufacturers, still, unhappily, existent amongst us.

OUR BOOK SHELF.

Catalogue of the Specimens illustrating the Osteology of Vertebrated Animals, Recent and Extinct, contained in the Museum of the Royal College of Surgeons of England. Part III., Class Aves. By R. Bowdler Sharpe, LL.D. (London: Printed for the College and sold by Taylor and Francis, Red Lion Court, Fleet Street, 1891.)

THE first point of interest in looking into this Catalogue was to ascertain which of the innumerable schemes of bird classification had been adopted by the author; we have so many of them nowadays. Sometimes they come upon us two at a time; and to make confusion worse, aged schemes of classification, which one hoped had long ago sunk into a dishonoured grave, are sprung upon us in a fresh edition. The plan followed by Dr. Sharpe is that of Mr. Seebohm, "elaborated in his 'Birds of the Japanese Empire,'" with a few modifications. Under each order is the diagnosis; and there are a few references to the anatomical literature of the subject, which is an addition to the value of the work. These are not very full, but perhaps it is hardly necessary that they should be. A feature of this catalogue is the introduction of illustrations; there are a good many of these—48 in all. They are for the most part figures of the skull, but the syringes of a few birds and the deep plantar tendons of more are also illustrated; two figures illustrate pterylosis, and two more the under surface of the foot. The illustrations in every case are good. The Catalogue is not encumbered with huge lists of synonyms: there is only the most recently accepted name given, together with a few of the most important synonyms. The collection of bones consists of 2380 specimens, representing altogether a little over one thousand species. Some of the fossil forms are of course represented by casts only; but a number of important extinct species, notably among the Dinornithidæ, are well represented by the actual remains, in many instances the types of the species in question. We may point out to the charitably disposed that there are a number of desiderata: there are, for example, no specimens of either the African or the American "Fin-foots."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Line Spectra of the Elements.

THE proper replies to Prof. Runge's letter in last week's issue of NATURE are three in number: viz. (1) that, as I pointed out in my former letter (NATURE of May 12, p. 29), the reasoning in my paper is valid if, as I there proved and as Prof. Runge now admits in the first sentence of his letter, Fourier's theorem can be applied to motions which approximate to non-periodic motions in any assigned degree and for any assigned time; (2) that I am not aware of anything I have written which countenances Prof. Runge's supposition that "Prof. Stoney has not noticed that a distinct property of the function is wanted in order to get a proper" [rather, a mathematically accurate] "resolution into a sum of circular functions"; and (3) that Prof. Runge is mistaken when he supposes that "the amplitudes and periods" [or frequencies] "of the single terms . . . do not approach definite values when the interval" [*i.e.* the periodic time of the recurrence required by Fourier's theorem] "increases indefinitely."

What the true state of the case is, is most easily shown as regards the frequencies of the lines; and as the proof is, I believe, new, and leads to a result of importance in the interpretation of spectra, I subjoin it.

Take a motion of the electron—

$$x = \text{The sum of partials such as} \left(a \sin \frac{2\pi kt}{j} + b \cos \frac{2\pi kt}{j}\right); \quad (1)$$

with similar expressions for the other two co-ordinates; in which the oscillation-frequencies, the k's, may be commensurable with one another, or incommensurable. If incommensurable, the motion is non-recurrent. Let this motion be arrested at intervals of T, and immediately started afresh as at the beginning. We thus obtain a recurrent motion consisting of a certain section of the motion (1) repeated over and over again. This new motion can be analyzed by Fourier's theorem, and we have to inquire what we thus obtain. Without losing anything in generality, we may confine our attention to the motion parallel to the axis of x, and to the single partial of that motion which is written out above, as all the partials lead to similar results.

Let us then examine by Fourier's method the motion which is represented by the equation—

$$x_k = a \sin \frac{2\pi kt}{j} + b \cos \frac{2\pi kt}{j} \quad . \; . \; . \; . \; . \; (2, a)$$

from $t = 0$ till $t = \mathrm{T}$, and which is repeated from that on at intervals of T. If T is a multiple of j/k, Fourier's theorem simply furnishes equation (2, a) as the complete expression for all time of the motion; so that in this case it indicates the same definite line in the spectrum as is furnished by the original partial of equation (1).

If T is not a multiple of j/k,

$$\mathrm{T} \text{ will} = (m + \alpha)\frac{j}{k},$$

where m is a whole number and α a proper fraction. Equation (2, a) then becomes

$$x_k = a \sin \frac{2\pi(m + \alpha)t}{\mathrm{T}} + b \cos \frac{2\pi(m + \alpha)t}{\mathrm{T}} \quad . \; . \; (2, b)$$

which is true from $t = 0$ till $t = \mathrm{T}$, after which the motion is to be repeated. Then, by Fourier's theorem—

$$\left.\begin{aligned} x_k = \mathrm{A}_0 + \mathrm{A}_1 \sin \frac{2\pi t}{\mathrm{T}} + \mathrm{A}_2 \sin \frac{4\pi t}{\mathrm{T}} + \; . \; . \; . \\ + \mathrm{B}_1 \sin \frac{2\pi t}{\mathrm{T}} + \mathrm{B}_2 \sin \frac{4\pi t}{\mathrm{T}} + \; . \; . \; . \end{aligned}\right\} (3)$$

is true of this motion for all time, in which

$$\mathrm{A}_n : \int_0^{\mathrm{T}} \sin^2 \frac{2\pi nt}{\mathrm{T}} \,.\, dt = a \int_0^{\mathrm{T}} \sin \frac{2\pi(m + \alpha)t}{\mathrm{T}} \,.\, \sin \frac{2\pi nt}{\mathrm{T}} \,.\, dt$$
$$+ b \int_0^{\mathrm{T}} \cos \frac{2\pi(m + \alpha)t}{\mathrm{T}} \,.\, \sin \frac{2\pi nt}{\mathrm{T}} \,.\, dt;$$

$$\mathrm{B}_n \,.\, \int_0^{\mathrm{T}} \cos^2 \frac{2\pi nt}{\mathrm{T}} \,.\, dt = a \int_0^{\mathrm{T}} \sin \frac{2\pi(m + \alpha)t}{\mathrm{T}} \,.\, \cos \frac{2\pi nt}{\mathrm{T}} \,.\, dt$$
$$+ b \int_0^{\mathrm{T}} \cos \frac{2\pi(m + \alpha)t}{\mathrm{T}} \,.\, \cos \frac{2\pi nt}{\mathrm{T}} \,.\, dt;$$

which, when integrated, give the following values for A_n and B_n—

$$\left.\begin{aligned} \mathrm{A}_n &= \frac{a \sin 2\pi\alpha - b(1 - \cos 2\pi\alpha)}{2\pi}\left(\frac{1}{d} - \frac{1}{s}\right) \\ \mathrm{B}_n &= \frac{a(1 - \cos 2\pi\alpha) + b \sin 2\pi\alpha}{2\pi}\left(\frac{1}{d} + \frac{1}{s}\right) \end{aligned}\right\} \; . \; . \; . \; (4)$$

where d stands for $(m - n + \alpha)$, and s for $(m + n + \alpha)$.

This furnishes a very remarkable spectrum, a spectrum of lines that are equidistant on a map of oscillation-frequencies, and that extend over the whole spectrum. But they are of very unequal intensities. If T is a long period, m is a high number. The lines are then ruled close to one another, and their intensities are insensible except when n is nearly equal to m, the two brightest lines being the next to the position of the original line of equation (1), one on either side of it, and the others falling off rapidly in brightness in both directions.

If we take a longer period for T, m becomes a still higher number; the lines are more closely ruled and are more suddenly bright up to those on either side of the position of the original line of equation (1), to which also they are now closer; so that, at the limit, when T increases indefinitely, equation (3) becomes a mathematical representation of the original line of equation (1).

This interesting investigation is all the more important as it gives a clue to how rulings of lines which are equidistant and brighter up to the middle may arise; and I feel sure that Prof. Runge will join me in not regretting that he expressed the doubts which led to its solution.

G. JOHNSTONE STONEY.

9 Palmerston Park, Dublin, June 3.

Stone Circles, the Sun, and the Stars.

ARTICLES by Mr. Norman Lockyer and Mr. Penrose, recently published in NATURE, have dealt with the positions of ancient Egyptian and Greek temples with relation to the rising sun, and to the pole star, or some star or stars in its vicinity. For some years past I have endeavoured to show, in papers read before the British Association and other Societies, that our stone circles had a relation to the rising sun, indicated usually by an outlying stone or by a notable hill-top in the direction in which the sunrise would be seen from the circle, and I have in some cases found similar indications towards the north, which may have referred to the pole or other northern star or stars. A paper containing many details as to these cases will shortly appear in the Journal of the Royal Archæological Institute.

There are six circles on Bodmin Moors, which at first sight appear to have no relation to each other, but which, if the 6-inch Ordnance map is to be relied upon, would seem to have been arranged on a definite plan (see accompanying plan).

The Stannon and Fernacre Circles are in line 1° (true) north of east with the highest point of Brown Willy, the highest hill in Cornwall; and the Stripple Stones and Fernacre Circles are in line with the summits of Garrow and Rough Tor, at right angles with the other line—namely, 1° west of (true) north. A line from the Trippet Stones Circle to the summit of Rough Tor would also pass through the centre of one of the Leaze Circles (about 12° east from true north). Other hills are in the direction of the rising sun. The Trippet Stones are 11½° south of west from the Stripple Stones, 10° east of south from the Stannon Circle, and about 13° west of south from the Fernacre Circle. The respective bearings of the other circles have already been given, and all are true (not magnetic) according to the 6-inch Ordnance map.

More remarkable, perhaps, than the position of these circles are their distances from each other, which, on the level map, are almost exactly as 3, 7½, 2, and 8, for the sides of the irregular four-sided figure, of which four of the circles form the corners, while the diagonals are of the same length within a hundred feet, the differences being much less than the 1 per cent. which Mr. Flinders Petrie has found to be the average error of ancient British and even Assyrian workmanship. The builders of these circles may be supposed to have aimed in their measurements at even numbers of some unit, and the unit which gives the best results appears to be a Royal Persian or Egyptian cubit of 25·1 inches (not at all the unit one would expect). The actual measurements, as nearly as I can get them from the 6-inch Ordnance map, are:—

	Feet.	Cubits of 25·1 inches.
Stannon Circle to Fernacre Circle ...	6275 =	3000
Fernacre Circle to Stripple Stones ... (Practically 7500 cubits)	15730 =	7520
Stripple Stones to Trippet Stones ... (Practically 2000 cubits)	4180 =	1998·4
Trippet Stones to Stannon Circle ... (Probably meant for 8000 cubits)	16575 =	7924
Diagonals.		
Fernacre Circle to Trippet Stones ...	16950 =	8103
Stannon Circle to Stripple Stones ... (Perhaps meant for 8125 cubits)	16550 =	8055

It must not be forgotten that these measurements are taken from the level map, while the ground between the circles is very irregular, but it seems more probable that the builders of these circles made allowance for the irregularities of the ground than that the distances, as shown by the map, are merely the result of accident.

If, however, the 25·1 inch cubit were the unit of measurement for the distances between the circles, it ought to appear in the measurements of the circles themselves—and it does; for the diameter of the Trippet Stones Circle is exactly fifty of such cubits, and the diameters of the Fernacre and Stripple Stones Circles are (as nearly as I can judge in their ruinous condition) seventy of such cubits.

The Egyptians appear to have constructed separate buildings for the observation of the sun and of the stars, but if the circle builders used the same circles for both purposes, placing them so that when standing in them they could see the sunrise over a fixed point on one hill, and a certain star rise over a fixed point on another hill in another direction, their system was much more economical, though perhaps less exact than that of the more civilized Egyptians.

A. L. LEWIS.

The Height of the Nacreous Cloud of January 30.

THE cloud referred to by Mr. T. W. Backhouse, in your issue of February 18 (p. 365), attracted universal attention over Eastern Yorkshire and even in Lincolnshire, so that numerous letters were sent to the *Leeds Mercury*, *Yorkshire Post*, &c.

Its general appearance in these parts is being dealt with by Mr. H. Bendelack Hewetson, of Leeds. I will therefore merely state that the intensity of the fringes surpassed anything in my previous experience. Even those observed in 1884–85, in connection with the Krakatão glows, did not approach it in this respect.

Here, as it happened, Venus lay just upon its lower edge. As this was fairly horizontal, save for a break not far from the middle, I was very pleased to get from Mr. C. J. Evans, Ackworth, near Pontefract, a second observation. In response to further appeals, observations, of varying accuracy, from the places in the subjoined table, were available for calculating the height.

Leeds (Prof. A. Lupton saw the cloud "nearly overhead," "if not, a little S.S.W.," "within 20° of the vertical"), *Ackworth*, and *York* enable us to determine the direction and position of the central part of the lower edge of the cloud as seen from the north and east. They give a point just above Mirfield Junction, 9 miles S.S.W. from Leeds, 32 miles S.W. from York and 13½ miles W. of Ackworth. The Driffield direction passes the same spot. The only other record, Market Rasen, is very divergent, the observer there putting the centre point south of west, whereas Mirfield is north of west.

The altitude of this point was capable of closer determination, thanks to references to Venus and Jupiter. The results of careful reductions are given in degrees in the following table, accompanied by the corresponding heights in miles, and distances and directions from Mirfield.

Place.	Miles from Mirfield.	Direction from Mirfield.	Altitude in degrees.	Resulting height above Mirfield.	Observer.
[1]Ackworth ...	13½	E.	40° (?45°)	11 (?13½)	C. J. Evans, &c.
[1]Tadcaster ...	22	N.E.	35°–40°	15	C. Rawson.
[1]York	32	N.E.	22½°	13½	J. E. Clark.
Wetwang ...	50	E.N.E.	16½°	15½	E. M. Cole.
Driffield ...	56	E.N.E.	10°–15°	16	J. Lovell.
Hull	54½	E. by N.	12°	13	S. Bowen.
[1]Market Rasen	58	E.S.E.	16°	15	W. Whiteman.
[1]Sunderland ...	88	N. by E.	7½°	14	T.W. Backhouse.

The adopted height from the above eight records is 14 miles, or 75,000 feet.

The Leeds record gives 25 miles, but Prof. Lupton wrote only from memory, in response to inquiry after some interval. It may, however, indicate that the south-west edge of the cloud was more nearly above Leeds. By shifting it 4 miles in that direction the Leeds height becomes 16 miles, and that for Ackworth 11½ miles, Tadcaster 12½, York 12, and the rest, except Market Rasen (unchanged), become half a mile less. The mean result, taken as before, but now including Leeds, is 13·6 miles, or substantially the same.

---

[1] As the records at these stations appeared to be much the more trustworthy, *double weight* is given them in the reduced value. In the Ackworth value, four times the weight is assigned to the 40° as to the 45°, the latter, on inquiry, being stated to be less probable.

The more distant localities did not, of course, view the same *edge* as those nearer, but one which must have been rather nearer them and lower down. Thus they are subject to a positive and a negative source of error, which cannot be well estimated, but which fortunately tend to neutralize each other.

The resulting height is unexpected, but the records agree so nearly as to leave little doubt of its substantial accuracy. Mr. Backhouse's measurements were made merely for altitude and an hour later, but the cloud-shift was so slight that it has been included. J. EDMUND CLARK.

A Dust Storm at Sea.

A FEW days ago, while returning to Tokio from the southern part of Japan, I joined the s.s. *Yokohama Maru*, which, whilst crossing from Shanghai to Nagasaki had passed through a curious dust storm. Small quantities of the dust were yet to be seen in sheltered corners of the vessel. The commander, Captain R. Swain, who gave me a specimen of the material, told me that on April 2, when about 95 miles west by south of Nagasaki (long. 128° E., lat. 32° 20′ N.), at about 6 p.m. the sun appeared quite yellow. The atmosphere was moist, and rendered everything upon the deck of the ship quite damp. The precipitated moisture was yellowish, and as it dried it left an extremely fine powder. For two days previously the wind had been blowing west-south-west, or from China. Nothing was felt in the eyes, and if the ship had not been covered with yellow powder, the phenomenon would have been regarded as an ordinary but peculiarly coloured fog.

The yellow atmosphere was noticed during the afternoon of the 2nd. At midnight the wind changed to north-west—that is, from Corea. The probability, however, is that the material came from the loess plains of China. In Nagasaki, which is 390 miles from the coast of China, a yellow sun was noticed on the morning of the 2nd; and during the day, whilst dust was being precipitated, the appearance of the atmosphere was compared to that of a London fog.

On April 1 there was a fall of dust in the neighbourhood of Nawa in Okinawa-ken, and on the 2nd dust fell in Gifu—the district where the recent great earthquake took place. The P. and O. s.s. *Verona*, which left Hong Kong on April 1, experienced the same phenomenon as the *Yokohama Maru*, the vessel being covered with a fine dust, which, when suspended in the atmosphere, gave rise to so much haze that land was not seen until reaching Nagasaki. On April 3 a yellow sun was seen in Yokohama, but I am not aware that any dust was observed. Roughly speaking, it therefore seems that on April 2, at a distance of from 200 to 400 miles from the coast of China, there was a cloud of dust which may have been over 1000 miles and possibly 2000 miles in length. Dr. B. Koto, who examined a specimen, tells me that the particles are chiefly felspar, but there is a little quartz and shreds of plants. JOHN MILNE.

Tokio, April 23.

Submerged Forest.

DURING a recent visit to an East Lincolnshire seaside place, Mabelthorpe, the remains of a submerged forest were pointed out to me plainly visible at low water. On closer inspection, the stumps of fallen trees, firmly embedded in the clay from one to twenty inches above the surface could be traced along the low-water level. I should be much obliged if any reader could fix a date at which the forest was growing. Does it not prove a subsidence of land in the neighbourhood? M. H. M.

Carnivorous Caterpillars.

I SHOULD like to know if it is a known fact that some caterpillars are carnivorous, eating their own kind, and small ones of another kind? I have found on a lime-tree on our lawn, six caterpillars, two of which have done so.

One of them has (though there was plenty of food, as I had only taken it from the tree a few minutes) eaten one of its own kind about three-quarters its own size; and later on in the day a small green looper (off the lime-tree), which was in the same box. A second has eaten two small loopers. The other three I only found to-day, and they are not as large as those which had eaten their fellows.

I cannot find a description of this caterpillar in "Das Buch der Schmetterlinge" (Lutz), which I use.

They are of a bright green, the colour of the young lime leaves, with a narrow white line down the back and along each side half-way down, and a broader one lower down. Between this and the narrow side-stripe are three very small black spots; between the back line and the narrow side-line, are two black spots, to each segment. Each spot has a white edge. On the first two segments the upper two spots are one under the other; but on the rest are side by side. The three spots form an L, with the two lower ones very near, or on the broad side-line.

They have eight prolegs, as well as the two suckers at the back. They appear very irritable, and swing their heads from side to side when touched, and apparently nip other caterpillars which dare to touch them in any way.

I may also mention that there are three very fine specimens of the Red Admiral (*Vanessa Atalanta*) in our garden to-day and yesterday. JULIET N. WILLIAMS.

Blackbrook, Bickley, Kent, May 29.

THE HURRICANE IN MAURITIUS.

THE devastation caused by the hurricane in Mauritius was so terrible that it was hardly to be expected the Observatory would be spared. We are glad to say, however, that it suffered no damage; and all meteorologists will congratulate themselves that the well-known Director, Mr. Meldrum, was able without delay to prepare an account of the storm. The account is printed in the special overland edition of *The Merchants and Planters Gazette*, May 11. We here reproduce it:—

"*Saturday, April* 30.

"The hurricane which raged for a few hours yesterday, April 29, has in many respects been unprecedented in Mauritius.

"Never till now has the island been visited by a hurricane at any time between April 12 and December 1. Hitherto the hurricane season of Mauritius has been supposed to begin on the latter and to end on the former day, and till yesterday there has been no exception to the rule.

"Nor was there any sign of danger till yesterday, when the barometer began to fall rapidly and the wind to increase to a heavy gale. The suddenness, rapidity, and extent of the changes which took place in a few hours are unparalleled in the annals of the colony.

"The following table will for the present suffice to convey some idea of the changes which took place in the barometric pressure and the direction and velocity of the wind from 9 a.m. on the 24th to 9 p.m. on the 29th:—

Day and Hour.	Barometer.		Wind.	
	Cor. and reduced to sea-level.	Fall or Rise per hour cor. for var.	Mean Direction.	Velocity in miles per hour.
	Inches.			
April 24				
9 a.m.	30·059	—	E.S.E. ½ S.	3
April 27				
9 a.m.	29·903	—	E. by S.	15
April 28				
9 a.m.	·905	—	N.E. by E.	12
4 p.m.	·816	−0·003	N.E. by E.	14
9 p.m.	·850	−0·006	N.E.	12
April 29				
6 a.m.	·660	−0·018	N.E. by E.	22·4
8 ,,	·630	−0·029	N.E. ½ E.	34·7
9 ,,	·576	−0·063	N.E. by E.	35·0
10 ,,	·480	−0·094	E.N.E. ½ N.	40·0
11 ,,	·338	−0·131	N.E. by E.	52·0
Noon	·066	−0·251	N.E. ½ E.	68·0
1 p.m.	28·517	−0·532	N.E. ½ E.	96·5
2 ,,	27·990	−0·513	N.	56·0
3 ,,	28·034	+0·048	W.N.W.	68·0
4 ,,	·520	+0·483	W.S.W.	112·0
5 ,,	29·059	+0·529	S.W.	82·0
9 ,,	·719	+0·151	S. Wrd.	26·0

"In the above table the fall or rise in the barometric pressure is corrected for the daily variation, and from 9 a.m. on the 24th to 9 a.m. on the 29th the mean hourly velocities of the wind are given, whereas from 10 a.m. to 5 p.m. on the 29th the rates of the velocity per hour are given as obtained from observations taken during intervals of two to five minutes.

"It will be seen that at 2 p.m. on the 29th the barometer was at 27·990 inches; that from noon to 2 p.m. it fell 1·045 inch; that from 3 to 5 p.m. it rose 1·012 inch; and that from 5 to 9 p.m. it rose ·660 inch. The absolutely lowest pressure was 27·961 inches at 2.30 p.m., which is the lowest on record in Mauritius.

"From 9 a.m. on the 28th to 1 p.m. on the 29th the mean direction of the wind did not vary much, but it occasionally showed a tendency to veer towards north, being at times from north-east by north to north-north-east. Between 1 and 2 p.m. it on the whole veered to north, and between 2 and 3 p.m. to west-north-west, oscillating considerably, and soon after settling down at west-south-west.

"After 11 a.m. the velocity of the wind increased much, being at 1 p.m. at the rate of 96·5 miles an hour, and at 1.20 at the rate of 104 miles. But from 1.25 to 2.30 p.m. there was a lull, the velocity decreasing to the rate of 43 miles an hour at 2.33 p.m. It then began to increase again, and at 3.47 p.m. was at the rate of 121·2 miles per hour, but it soon began to abate, being at the rate of 72 miles at 5·20 p.m., 60 miles at 6 p.m., 47 miles at 7 p.m. and 26 miles at 9 p.m. By this time the weather was fine, the sky partially clear, and here and there stars shining brightly.

"Seeing that from 9 a.m. on the 24th to 9 a.m. on the 27th the barometer had fallen from 30·059 to 29·903 inches, and that the wind, though light, had veered from east-south-east half south to east by south, a note was sent to the newspapers on the latter day, stating that there was heavy weather to the northward, and that it had existed since the 24th; which, as usual in such circumstances, meant that there were indications of a cyclone away to the northward and that it was travelling from north-eastward to south-westward.

"But the wind having by 9 a.m. on the 28th reached north-east by east, and the barometer being higher on the 27th at the same hour, there was no apprehension; and in the afternoon of the 28th, the wind being still moderate from north-eastward, and the barometer falling at the rate of only 0·003 inch per hour, it was announced that there was no fear.

"As already stated, it was only on the 29th that the conditions became unfavourable, and at 9.40 a.m. a telegram was despatched announcing that the barometer was falling at an accelerating rate.

"Other telegrams, despatched at 11 a.m., announced that the velocity of the wind was at the rate of 52 miles an hour in the squalls, and that probably it would not exceed 56 miles an hour. Soon afterwards the telegraph wires were broken, and all communication ceased.

"The barometer continuing to fall at an accelerating rate, and the mean direction of the wind being nearly constant, it was inferred that the centre of the depression would, contrary to long experience (the wind being from north-east) pass over the island, and that the wind would then come from nearly the opposite direction.

"The centre, however did not pass over the Observatory, but over a point about six miles to the westward of it, and apparently from that point it travelled across the island on an east-south-easterly course.

"As a rule, when the wind is from north-eastward, there is scarcely any danger of a hurricane in Mauritius. All our great hurricanes have commenced, not with a north-easterly, but with a south-easterly wind; and this is why, when the wind was from north-east by east at 11 a.m. yesterday, and the barometer at 29·338, it was considered probable that the velocity of the wind would not exceed 56 miles an hour. On February 12 last, the barometer fell to 29·325, and the greatest velocity of the wind was 47·5 miles per hour from north-east, the barometer soon afterwards rising and the wind decreasing.

"There are, apparently, only two ways of, in a measure, accounting for the passage of the centre of a hurricane over the island yesterday from west-north-westward to east south-eastward. Firstly, the cyclone which had been travelling to the northward and north-westward of the island on a south-westerly course, from the 24th to the 27th, recurved to the southward and south-eastward; or secondly, a small secondary cyclone, which was generated in the south-east quadrant of the larger cyclone, travelled to the east-south-eastward, and bore down on Mauritius. The latter is perhaps the more probable hypothesis; for the small but violent hurricane of yesterday, with respect to its extent, duration, &c., exhibited the characteristics of a local atmospheric disturbance.

"On the night of the 27th and morning of the 28th there was a great deal of thunder and lightning, and also frequent lightning during the night of the 28th. But the hurricanes of Mauritius are seldom, if ever, immediately preceded by thunder and lightning.

"It may be stated, also, that from the 25th to the 29th there were from five to six groups of sun-spots, indicating a considerable increase of solar activity; and that from the 25th to the 28th there were large magnetic disturbances, the portion of the sun's disk on which there was a very large group of spots on February 12 being again on or near the sun's central meridian.

"C. MELDRUM."

PROFESSOR JAMES THOMSON.

PROF. JAMES THOMSON, who died on May 8, after a few days' illness, the result of a chill, was born in Belfast in 1822. He was the son of James Thomson, who was then Lecturer on, and afterwards Professor of, Mathematics in Belfast, and subsequently became Professor of Mathematics in Glasgow University. The father was a highly successful teacher and original investigator in mathematics, and was the author of many important school books. One of these books was, thirty years ago, still the recognized text-book on arithmetic in Ireland, and in all probability still retains its position. It was referred to by its very well-known title the "Thomson," by Prof. Tyndall in his British Association Address in 1874. We do not need the assurances of contemporaries, which are plentiful, that the two boys, James and William Thomson (now Lord Kelvin), made brilliant progress in their father's subject, and exhibited, even in early days, that combination of inventive genius and painstaking effort for accuracy, which have been their great characteristics since. James took his M.A. degree at Glasgow, served an apprenticeship under Sir William Fairbairn, and practised in Belfast as an engineer. He held the appointments of engineer to the Belfast Water Commissioners and to the Lagan Canal Navigation Works. In 1857 he became Professor of Civil Engineering in Queen's College, Belfast, and his Belfast pupils are to be found occupying high positions in every part of the world. He succeeded Rankine in Glasgow in 1872, and resigned the Professorship at Glasgow in 1889 because his eyesight was failing. He became a Fellow of the Royal Society in 1877. He received the honorary degrees of D.Sc. from the Queen's University of Ireland, and of LL.D. from Glasgow and from Dublin. In 1853 he married the only daughter of the late Mr. William John Hancock, J.P., of Lurgan, Co. Armagh, and it is a pathetic circumstance connected with his death, that she and one of his daughters survived him only a few days. He leaves a son and another daughter.

In his private engineering practice at Belfast, he carried out important work in hydraulic machinery for use at home and in foreign countries. He invented the inward flow vortex turbine, and even now there are men in Ulster who are willing to talk at great length about his troubles and successes with this turbine. There was no practical man, however clever, who did not at first ridicule the scientific young gentleman who proposed to replace an eighty foot wheel by a tiny turbine, whose wheel was less than a foot in diameter. He never in his life could have had a happier moment than that in which, surrounded by crowds of astonished rustics and practical engineers, he saw this tiny wheel in its very first trial, driving the machinery of a large mill. And now, wherever turbines are to be found all over the world, they are mostly "Thomson" turbines, made on the principles so clearly thought out and described by him, albeit they are known under many very different names. His notions on such subjects as strength of materials and the effect of initial strains in materials, although published forty-four years ago, have only lately become the notions of practical engineers. At that early date, his ideas on many of the applications of science in engineering were very clear and correct, and far in advance of his contemporaries. He is especially to be recognized for his services in practical hydrodynamics, a subject in which there has been a more misleading appearance of mathematical theory than in any other branch of engineering. To one of Thomson's pupils it is positively painful to take up any authoritative treatise on hydraulic machinery, for he knows that nearly every page of troublesome mathematical reasoning is based on some absurd assumption, and that James Thomson's few propositions are almost the only ones on which the engineer can rely. James Thomson seemed to fear the misuse by young engineers of the recognized mathematical methods of attacking physical problems. He, himself, when he used mathematical expressions, used them merely to put before others the results of his own method of reasoning. It expresses only a part of the truth to say that he thought about things geometrically rather than algebraically. He refrained from publication until his proof was perfect, and some of his pupils may feel sorry that they have not more faithfully followed their master's example. A study of his successive manuscript proofs of his law of flow of fluids from similar orifices would probably enable us to conceive of the habits of thought of the Greek geometers: every word and phrase is carefully selected, and considered time after time with a view to perfect accuracy. Such invention and such regard for perfection of detail were surely never combined before.

When any of his speculations has been once published in an authoritative text-book, it will be noticed that it appears in all text-books published subsequently; the melting point of ice, the triple point in water-stuff, the continuity in the steam water isothermal, the tears of strong wine, are a few examples. No doubt, as time goes on, text-book writers will find that he discovered other important things. He was such a very observant man that he often put forward his most important propositions when explaining phenomena that seemed utterly insignificant. Let the reader only think that what occurs in a wash-basin, or in a little rivulet near the sea, may be of great importance scientifically, and let him read again some of Thomson's insignificant-looking scattered papers, and he will find important propositions published which will not, perhaps, for some years yet, find their proper positions in the text-books.

Of the history of thermodynamics during the eventful years 1849–50, who dares now to say anything? Nor can anyone now say anything about the great glacier dispute. One thing is certain, however, that James Thomson's discovery of the necessary lowering of the melting-point of ice with pressure, published on January 2, 1849, settled for ever the theory of the flow of glaciers. Joule's work was beginning to be known, but Thomson, in his proof, like Lord Kelvin in the well-known paper published on the same day, adopts Carnot's idea of the conservation of heat. A change in one expression, not essential to the proof itself, was all that was needed after the first and second laws of thermodynamics had been recognized. Of his various papers on hydrodynamics, capillarity, heat, light, and the states of matter, published since that time, we have not space to say more than that each of them made a substantial addition to our knowledge. His latest work, the Bakerian Lecture this year of the Royal Society, on "The Grand Currents of Atmospheric Circulation," is such a paper as we might expect from a man who had given more than thirty-five years of study to the subject, that subject being one which was peculiarly his own. It is possible that the practical engineer, judging from the title merely, may neglect to read a paper which is one of phenomenal importance to the engineer as well as to the physiographer.

He was a man of singular purity of mind and simplicity of character, very clear-sighted in all that pertained to moral right and wrong, and conscientious to a degree. In his presence one felt in a purer atmosphere, where mean things seemed impossible. No Professor was ever so willing to take trouble (not mere momentary trouble, but trouble of days and nights) in the interests of a student, but no Professor was ever so rigidly exact in giving certificates and testimonials. The present writer has talked often with his old pupils about him, but never met one of them, who, besides a great respect, had not also a genuine and kindly and pleasurable love for his old Professor, whose kindness and patience had been unfailing, and whose sympathy had many a time been extended to him. How useless it is to speak of the good done to the world by a man of his character. Every one of his pupils, in however small or great a degree, is extending the range of his influence.

JEAN SERVAIS STAS.

THE regret expressed in the obituary notice of Jean Servais Stas, that we had not the exact words of his famous discourse delivered before the King of the Belgians, has attracted the attention of a correspondent, who has very courteously sent us the text of the speech.

It was delivered by J. S. Stas in his capacity of President of the Royal Academy of Sciences, and was addressed to the King at the New Year's reception, January 1, 1891. We have much pleasure in laying a translation of it before our readers:—

"Sire,

"The Royal Academy of Science, Literature, and the Fine Arts expresses its sincere wishes for the happiness of your Majesty, and the prosperity of your reign.

"As the central organ of the intellectual movement of the country, the Academy seeks to comprise within its arms the most varied talents, and to remain always an adequate and living expression of the entire activity of the human mind.

"This is both its duty and the reason for its existence.

"In the sphere of Literature and Art its voice is almost always safely guided by public opinion—a competent judge of works accessible to all.

"It is otherwise in the sphere of Science.

"The physical, mathematical, and natural sciences, and even the moral and political sciences, do not appeal in the same degree to public opinion. If their conquests radiate afar, if they incessantly modify the conditions of social existence, they themselves develop in restricted circles, and work out of sight and of knowledge of the multitude.

"The Universities, Sire, in our country especially, are the principal foci of scientific life. There not only the men of science of the future are trained, but the present representatives of higher research work, create, and distinguish themselves. There also the Royal Academy by preference seeks its fellows to associate them in its task and to render it fruitful.

"Its mission cannot be divorced from that of the institutions for higher education, and their lustre and their decline are simultaneous.

"In the name of this great and twofold interest the President of the Royal Academy feels bound to call the attention of your Majesty to the mode of appointment to the professorial chairs in the State Universities.

"The method adopted is absolutely faulty, and it affords to Science none of those guarantees which she has a right to demand.

"The intensity of party strife has the effect of absorbing into its vortex even those acts of the public authorities which ought to be least open to its influence. In place of conferring the University chairs upon the most capable men as their rightful prerogative, with the sole thought of raising the level of studies and of enlarging the intellectual patrimony of mankind, we too often see the spirit of faction disposing of such positions arbitrarily, to the injury of the scientific spirit.

"An incompetent professor paralyzes for a quarter of a century, even if he does not kill, instruction in the department committed to him. An improper nominee is a denial of justice.

"The courts of law have been invested with the right of presentation to vacant judgeships; an analogous prerogative ought to be conferred on the faculties of the Universities. Their choice would then be dictated by considerations essentially scientific, and to this end the Royal Academy relies on the great influence of the King."

"The King," adds the *Indépendance Belge*, "did not accept this appeal to his influence, and the Ministers present bestowed black looks upon the President of the Academy."

This impressive discourse has its lessons for us also, as it emphasizes the necessity of conferring scientific appointments purely in accordance *rebus gestis*, and in consideration of the actual work done by the candidate.

W. C.

NOTES.

The annual *conversazione* of the Royal Society will be held on Wednesday, June 15.

At the annual meeting for the election of Fellows, held on Thursday last, the Royal Society elected the fifteen candidates whose names, with the statement of their qualifications, we have already printed.

The British Medical Association will hold its sixtieth annual meeting at Nottingham on July 26, and the three following days. Mr. Joseph White, consulting surgeon of the Nottingham General Hospital, will preside. Addresses will be given, in medicine, by Prof. James Cumming, of Queen's College, Belfast; in surgery, by Prof. W. H. Hingston, of Montreal; and in bacteriology, by Dr. G. Sims Woodhead, of the Research Laboratory of the Colleges of Physicians and Surgeons, England. The scientific work of the meeting will be done in ten sections.

At a meeting of the American Philosophical Society, Philadelphia, on May 20, it was decided that the one hundred and fiftieth anniversary of the foundation of the Society should be worthily celebrated in 1893, and a committee was appointed to make the necessary arrangements.

The Federated Institution of Mining Engineers held their general meeting in London on Thursday and Friday last. At the meeting on Thursday papers were read on "Gold Mining in New Zealand," by G. J. Binns, and on "Petroleum in Eastern Europe and the Method of Drilling for it," by A. W. Eastlake. Prof. T. E. Thorpe gave some practical demonstrations of the action of coal-dust when exploded with gas. The members visited the Electrical Exhibition at the Crystal Palace in the afternoon, and dined together at the Garden Hall in the evening. Among the papers read at the meeting on Friday were papers on "The Causes of Spontaneous Combustion of Coal and Prevention of Explosion on Ships," by M. V. Jones; "A Safety-cage for Mines and Hoists," by J. Whitelaw; "Winding by Water-balance at Ynis Merthyr Colliery," by M. W. Davies; and "Gold Milling," by W. F. Wilkinson.

The Aldini Medal for Animal Electricity has been awarded to Dr. A. Waller, Lecturer on Physiology, St. Mary's Hospital Medical School, by the Bologna Academy of Sciences.

The Council of the Institution of Electrical Engineers decided that the Salomons Scholarship of £35 should be given to a second year's student training to become an electrical engineer at either King's College, University College, the City and Guilds Central Institution, or the Finsbury Technical College. The first award has just been made to C. H. C. Woodhouse, Matriculated Student of the Central Institution, Associate of the Royal College of Science, and B.Sc. of the London University.

At the annual meeting of the Institution of Civil Engineers Mr. Harrison Hayter was elected to act as President for the ensuing year. The Vice-Presidents are Alfred Giles, Sir Robert Rawlinson, Sir Benjamin Baker, F.R.S., and Sir Jas. N. Douglass, F.R.S. The following are the other members of Council:—W. Anderson, F.R.S., J. Wolfe Barry, Alex. R. Binnie, E. A. Cowper, Sir Douglas Fox, J. C. Hawkshaw, Charles Hawksley, Sir Bradford Leslie, George Fosbery Lyster, James Mansergh, Sir Guildford L. Molesworth, W. H. Preece, F.R.S., Sir Edward J. Reed, F.R.S., William Shelford, and Francis W. Webb.

In the official abstract of the report of the Council of the Institution of Civil Engineers for the session 1891–92, it is stated that 59 associate members had been transferred to the class of member, and that there had been elected 3 honorary members, 28 members, 324 associate members, and 7 associates, while 4 associate members had been restored to the register. These additions together amounted to 366. After deducting 145 names from deaths, resignations, and erasures, there was an increase of 221, bringing up the total number on the register to 5371, as against 5150 at the corresponding date last year. This enumeration was irrespective of the students, of whom 200 had been admitted during the year, as against 166 for the previous twelve months; but during this period, 106 students had become associate members, and 140 had disappeared from the list, so that the number now on the books was only 868, whereas last year the number was 914. Thus, including students, the total number on the books was now 6239, as against 6064 twelve months ago. The following awards have been made to the authors of papers which have been discussed:—A George Stephenson Medal and a Telford Premium to Mr. Alex. R. Binnie; Telford Medals and Telford Premiums to Mr. A. P. Trotter and Mr. W. T. Douglass; and Telford Premiums to Messrs. H. Alfred Roechling, A. H. Curtis, W. Airy, H. Gill, and Prof. W. C. Roberts-Austen. In respect of communications which have been deemed suitable for printing without being discussed, Telford Medals and Telford Premiums had been adjudged to

Messrs. F. Fox and Alfred W. Szlumper; and Telford Premiums to Messrs. Sheibner, T. H. Beare, W. C. Unwin, E. Penny, A. D. Stewart, R. H. B. Downes, and W. Matthews. The Howard Quinquennial Prize had been awarded to Sir Isaac Lowthian Bell, Bart., F.R.S., for his treatise on "The Principles involved in the Manufacture of Iron and Steel." The papers read at supplemental meetings of students had shown in nearly every case evidence of having been prepared with care. Three, at least, were of high merit, and, with four others above the average, had been deemed worthy of publication, either in whole or in part, in the Minutes of Proceedings. For these seven papers the Council have awarded the Miller Scholarship to Mr. H. B. Ransom for his paper on "Fly-Wheels and Governors," and Miller Prizes to Messrs. C. H. Wordingham, E. L. Hill, D. Carnegie, G. H. Sheffield, J. B. Ball, and R. J. Durley.

AT the second annual dinner of the Institute of Marine Engineers, held last Thursday, Lord Kelvin, the President, said in the course of his inaugural address that the institution was one which he thought could not fail to be of the greatest service to the cause of marine engineering. He had only to go back to the days of his youth to recall the immense strides which had been made in this great industry. His father was an Irishman, as he himself was, and he used to cross the Channel from his home in county Down as best he could to land at some point on the coast of Scotland and find his way to the University of Glasgow, there to pursue his studies. He used to make the passage in whatever sailing vessel he could find taking the cattle across, and the time of the passage was not part of the bargain. On one occasion he sailed from Belfast to Greenock in twelve hours; on another he was four days on the passage, and sailed three times round Ailsa Craig. It was only necessary to state such facts to show how vast had been the progress since those days. No branch of engineering, no branch of science which aimed at supplying the wants of mankind, had made greater progress in the last sixty years than that. He was not forgetting railways or telegraphs; but he said advisedly that no branch of engineering had made greater or more splendid strides than marine engineering.

MISS DOBERCK, who has been appointed assistant meteorologist in Hong Kong, is the sister, not the daughter, of the present Director of the Hong Kong Meteorological Observatory.

ACCORDING to a telegram from Naples, dated June 7, the eruption of Mount Vesuvius, which had been noticeable for some little time, had considerably increased in volume, and large masses of lava were flowing into the Atrio di Cavallo ravine.

ON June 7, at 12.30 a.m., an earthquake shock was felt at San Severo, in the province of Foggia, and an adjoining hamlet. The oscillations, which were of an undulatory character, created a temporary panic.

THE weather during the first part of the past week has been fine over the eastern and southern portions of England, but unsettled in Ireland and Scotland, with a considerable amount of rainfall, while the temperature was much lower, generally, than in the previous week, the daily maxima not exceeding 70°. On the morning of the 4th a disturbance appeared off the Irish coast and crossed our islands on Sunday, causing heavy rain in places, and thunderstorms in the eastern parts of England. The *Weekly Weather Report* for the week ending the 4th instant shows that during that period the rainfall exceeded the mean in all districts, excepting the east of England, where bright sunshine was very prevalent. Over Ireland and in the north of Scotland the excess above the normal rainfall was large, being 1·2 inch and 0·8 inch respectively, yet, reckoning from the beginning of the year, there was still a deficiency in all districts. On Monday, the 6th, a great increase of temperature occurred in most parts of this country, and the weather became much more settled, under the influence of an anticyclone which approached our islands from the southward, while the shade temperature in London reached 73° and 74° at Loughborough. During the early part of this week, the anticyclone became well established, and had caused the temperature to rise considerably in Scotland and Ireland, with prospects of settled, fine weather, generally.

MR. R. H. SCOTT has contributed an article, entitled "Notes on the Climate of the British Isles," to *Longman's Magazine*. The author gives some amusing instances of the distortion of facts at seaside stations, where the observers are anxious to prove the advantages of their own towns over those of their rivals. Taking the whole year round, the warmest spot is the Scilly Isles, which are a degree warmer than either the west of Cornwall or the Channel Islands; while the coldest region on the coast is the extreme north-east of Aberdeenshire. In winter very little difference of temperature is met with all along the east coast; but the coldest part of England lies round the Wash. With regard to the variability of temperature, or the difference of the mean temperature of an entire day, the equability of the temperature of these islands is very great. The only locality for which a more uniform temperature has yet been published is Georgetown (Demerara); the figure for this place is 1°·1, while for London it is 2°·7. All the great changes of temperature occur in winter, and accompany sudden thaws. As regards bright sunshine, the Channel Islands are by far the most favoured. On the mean of the whole year, Jersey secures 39 per cent.; but from the Bristol Channel to the coast of Norfolk there is but little difference in the amounts recorded. In cities like London the deficiency is due to smoke. The statistics relating to fog are not yet completely discussed, but so far as they go they show that in winter the foggiest district is the east coast of England. Next come London and Oxford, which are about equal. With regard to rainfall the east coast stations receive on an average of the whole year about half as much as those on the west coast, the amount being about 25 inches on the east coast, 30 to 40 inches between Sussex and Devonshire, and 50 inches to the south of Cornwall. In the west of Ireland the amount rises to 70 or 80 inches, owing to high land near the coast. The driest hour almost everywhere is noon.

MR. C. MICHIE SMITH has edited a work embodying "Results of the Meteorological Observations made at the Government Observatory, Madras, during the years 1861–90, under the direction of the late Mr. Norman Robert Pogson." The volume is published by order of the Government of Madras. It was Mr. Pogson's intention to issue the work as soon as he could after the completion of thirty years of observation, and at the time of his death a considerable part of the manuscript was nearly ready for press. In editing the work, Mr. Smith, so far as possible, has retained the original plan. He expresses much admiration for the skill and thoroughness with which the observations were organized and carried out.

THE Essex Field Club will probably hold its first dredging meeting of the season at Brightlingsea on Friday and Saturday, June 24 and 25. Other field meetings in course of arrangement are: Visit to Dagenham district (June or July); the Writtle Woods (July 30); Rochford and Rayleigh (August); on the Stour from Bures to Manningtree; visit to the Deneholes, &c.

THE Clarendon Press will publish immediately a second volume of Prof. Weismann's work on "Heredity and Kindred Biological Problems." It contains four essays, of which only the shortest has previously appeared in an English form (in the columns of NATURE). The first essay deals with degeneration, and clearly shows, by abundant illustrations, that it has resulted from *panmixia*, or the cessation of natural selection. The second is an attempt to explain the development of the art of music, and to show that the hereditary transmission of the results of practice is quite unnecessary in order to account for its rise. The third contains a reply to certain objections urged by Prof. Vines. It will be useful in giving clearer expression to the ideas on the death of multicellular beings and the immortality of the unicellular. The fourth and last essay is by far the longest and most important. It deals with the essential significance of sexual reproduction and conjugation, &c., as inferred from the results of the most recent researches. Prof. Weismann's older views on these subjects (especially concerning the polar bodies) have been modified and in part abandoned. The immortality of unicellular beings and the question of the transmission of acquired characters by them are also discussed in detail with reference to recent observations.

WE have received the first volume of the *Jahrbuch der Chemie*, a new periodical issued by the Frankfort publisher H. Bechhold. The editor is Prof. Richard Meyer, of Brunswick. Chemistry is now divided into so many departments that it is difficult for specialists to obtain an accurate idea of the recent progress of the science as a whole. The object of the *Jahrbuch* is to supply this need, and, if we may judge from the first issue, the work is likely to fulfil its purpose admirably. The editor has secured the co-operation of many well-known chemists, each of whom presents a general view of what was done last year in the department of research to which he himself is more particularly devoted. Thus there are, among other papers, reports on physical chemistry, by W. Nernst; on inorganic chemistry, by G. Krüss; on organic chemistry, by C. A. Bischoff; on physiological chemistry, by F. Röhmann; on pharmaceutical chemistry, by H. Beckurts; on agricultural chemistry, by E. F. Dürre; on explosives, by C. Häussermann; and on photography, by J. M. Eder and E. Valenta. In future issues the editor hopes to include the bibliography of each branch of the subject.

THE new number of Wundt's *Philosophische Studien* opens with a comprehensive paper by the editor on "Hypnotism and Suggestion." The subject is treated from the double standpoint of physiology and psychology; and the article should go far towards bringing about a saner tone of thought than that which is just now current, even in "educated circles." Mr. Titchener's chronometrical determinations reduce the recognition time of colours to 30, of letters and short words to 50 thousandths of a second. Dr. Merkel's article on the psychophysical error-methods is concluded; and Drs. Külpe and Kirschmann publish the results of a careful testing of the Hipp chronoscope (old pattern) by means of a new control-hammer.

ON Sunday last a terrible disaster overtook the petroleum district in Pennsylvania, especially the places called Oil City and Titusville. A thunderstorm, accompanied by torrents of rain, broke over the district, and the two cities were so quickly inundated by the swollen waters of Oil Creek that it was difficult for the inhabitants to escape to the hills, and many were drowned. Several refineries were struck by lightning, so that the unfortunate towns were devastated equally by fire and by water. It is supposed that about 200 persons lost their lives, while the destruction of property was enormous.

THE gallery in the South Kensington Museum assigned to the large collection of wrought iron work which has for some time been closed for rearrangement, was re-opened to the public on Whit Monday. The larger grilles and screens, including the gates from Hampton Court, are now placed in the arched spaces on either side, while the lanterns, cressets, signs, &c., are suspended along the gallery, smaller objects being shown in sloping glass cases. Among these last is a curious series of rush-candle holders, tobacco tongs, and other domestic implements used in England, chiefly in the eighteenth century, collected and lent by Lady Dorothy Nevill. Examples of the locksmith's art, English, French, and German, are numerous, including some chiselled steel locks and keys from old French buildings, but produced by "Johannes Wilkes de Birmingham" in the seventeenth century. Some of the more famous specimens of mediæval work in English cathedrals have been reproduced in facsimile. A hand-book on "Decorative Iron Work," prepared by Mr. Starkie Gardner, will shortly be published.

THE Board of Directors of the Zoological Society of Philadelphia have issued their twentieth report, and are able to give a good account of their work during the past year. Among the changes of the year was the establishment of "a cheap day," the price of admission on Saturdays and holidays (except the Fourth of July), having been fixed at ten cents for adults and five for children. The result has been satisfactory, the attendance having increased considerably, while there has been no material financial loss. Another fact noted in the report is that an offer of free admission to the Garden was made to the Board of Education for such classes of pupils of the public schools as seemed to the Board likely to profit by the privilege. Under the arrangement entered into, nearly ten thousand scholars of the public schools were admitted between September 23, when tickets were issued, and March 1, the end of the Society's fiscal year.

THE botanical section of the Imperial Museum of Natural History at Vienna is about to issue, under the name "Cryptogamæ, Exsiccatæ," a collection of named Cryptogams to its contributors, and in exchange for other similar collections.

THE Indian papers report that, under the auspices of the Government and Secretary of State for India, an important work, illustrative of the famous Ajanta Cave mural paintings, will be published shortly. The bulk of the work will consist of 173 imperial folio plates, mostly produced in chromo-collotype, by Mr. Griggs, of Peckham, the accompanying text being from the pen of Mr. John Griffiths and Dr. James Burgess, C.I.E.

FROM an official return just published it appears that during 1891 the total number of persons killed in the Punjab by wild beasts and snakes was 861, or one less than during the previous year. The great majority died of snake-bite, only 65 deaths being attributed to wild beasts. On the other hand, of the 966 cattle reported to have been destroyed, only 38 were killed by snakes.

MR. W. S. KEY calls attention, in the American journal *Electricity*, to the difficulty which manufacturers of electrical devices in the United States experience in obtaining iron adapted for electrical purposes. They complain of the inferior quality of the iron, the trouble in obtaining such brands as are in every way suitable, magnetically considered, for use in electrical devices such as dynamo and motor armatures, transformers, &c. They also complain of the irregular and unsatisfactory manner in which it is too generally annealed and finished by rolling, scaling, &c. Some of these manufacturers have for years used imported English, Welsh, and Swedish iron, which is necessarily of high price. They have also used Pennsylvania iron of high quality, but as yet have failed to discover just the quality they need. Mr. Key's experience in connection with a well-known firm in England has convinced him that iron such as is wanted in electrical manufactures might be produced if proper methods were adopted. "To secure such iron," he says, "of course a full and accurate knowledge of the qualities of the various brands of pig-iron now on the market would be a prime requisite; none the less would a correct knowledge of mixing be essential, while the rolling, scaling, and annealing would all have to be very carefully attended to if satisfactory results were to be attained."

An important series of bibliographies relating to the more prominent groups of the languages of the North American Indians, by J. C. Pilling, is being issued by the Smithsonian Institution. The numbers concerning the Eskimauan, Siouan, Iroquoian, and Muskogean families are already known to students of these languages; and now a fifth number, giving the bibliography of the Algonquian languages, has been published. The sixth will include the languages belonging to the Athapascan stock. The volume on the Algonquian languages contains 2245 titular entries, of which 1926 relate to printed books and articles, and 319 to manuscripts. It consists of 614 closely-printed pages, and represents an amount of well-directed labour for which Mr. Pilling deserves the cordial recognition of all who will in any way profit by his researches.

The atomic weight of copper has been redetermined by Dr. Richards, and an account of his work will be found in two papers contributed to the new *Zeitschrift für Anorganische Chemie* (pp. 150 and 187). From the results of experiments concerning the replacement of silver in silver nitrate by metallic copper, Dr. Richards was led to believe that the number usually accepted for copper, 63·3, was considerably too low. He has, therefore, thoroughly investigated the methods by which the old number was obtained, and made a new series of determinations, in which corrections have been applied for the errors due to the mode of analysis adopted. In the year 1874 Hampe made two series of determinations of the atomic weight of this element. One of these, in which the amount of metallic copper contained in copper oxide was estimated, gave the value 63·34; the second, which depended upon the copper content of anhydrous copper sulphate, yielded the number 63·32. The lower of these values has since been generally accepted as representing most probably the true atomic weight of copper, on account of the extreme manipulative care taken by Hampe, and the remarkable agreement of the individual experiments. Dr. Richards, however, has discovered a flaw in the method. Hampe dried his sulphate of copper at 250°; but Dr. Richards has experimentally proved that the so-called anhydrous sulphate obtained at this temperature loses about 0·17 per cent. of its weight when heated to the temperature of the vapour of boiling mercury. This loss, moreover, when taken into account in calculating the atomic weight, brings up the figure almost exactly to that indicated by the replacement of silver experiments. An exhaustive investigation has eventually shown that copper sulphate retains 0·12 per cent. of its water of crystallization, even after it has been subjected to a temperature of 400°. Indeed, this last trace of water is only eliminated at a temperature at which the sulphate itself commences to decompose. Dr. Richards has therefore made a series of redeterminations of the atomic weight by Hampe's method, drying the salt at 250°–270°. On calculating directly from the figures obtained, the experiments gave the mean value 63·35, a result almost identical with that of Hampe. But upon applying the correction for the slight amount of water still retained at this temperature the mean value is raised to 63·60.

In the second communication Dr. Richards discusses the mode of determining the atomic weight by ascertaining the amount of copper contained in copper oxide. He shows that copper oxide which is prepared by the method employed by Hampe, ignition of the oxynitrate, contains four or five times its volume of occluded gases, and that even at a bright red heat only a portion of this occluded gas can be expelled. Dr. Richards has therefore made a series of redeterminations by this method, applying the necessary correction for occluded gas, the correction having been very accurately ascertained from a large number of observations. The final mean value of the atomic weight of copper afforded by the whole of Dr. Richards's experiments is 63·604 (oxygen = 16), the maximum and minimum values being 63·609 and 63·600 respectively. If the value of oxygen is taken as 15·96, that of copper becomes 63·44.

The additions to the Zoological Society's Gardens during the past week include two Four-horned Antelopes (*Tetraceros quadricornis* ♂ ♀) from India, presented by Mr. H. M. Phipson, C.M.Z.S.; a Huanaco (*Lama huanacos* ♂) from Bolivia, presented by Mr. Frank Parish, F.Z.S.; a Black-necked Hare (*Lepus nigricollis*) from Ceylon, presented by Mr. T. C. Kellock; a Common Squirrel (*Sciurus vulgaris*), British, presented by Miss Ruxton; a Masked Parrakeet (*Pyrrhulopsis personata*) from the Fiji Islands, presented by Mr. A. B. Holdsworth; a Booted Eagle (*Nisaëtus pennatus*), European, presented by Lieutenant J. E. Rhodes; a Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. Frank Allen; a European Pond Tortoise (*Emys europæa*), European, presented by Miss Lilian Powell; two Alligators (*Alligator mississippiensis*, jv.) from Florida, presented by Mr. R. White; a Moloch Lizard (*Moloch horridus*) from Australia, presented by Mr. John McLey; a Llama (*Lama peruana* ♂) from Peru, an Ostrich (*Struthio camelus* ♂) from Africa, a One-wattled Cassowary (*Casuarius uniappendiculatus*), a Common Crowned Pigeon (*Goura coronata* ♂) from New Guinea, two Victoria Crowned Pigeons (*Goura victoriæ* ♂ ♀), from the Island of Jobie, two Narrow-barred Pigeons (*Macropygia leptogrammica*) from Java, two Pale-headed Parrakeets (*Platycercus pallidiceps*) from North-East Australia, two Roseate Spoonbills (*Platalea ajaja*) from South America, two Vociferous Sea Eagles (*Haliaëtus vocifer*) from West Africa, purchased; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Light-Variations of Y Cygni.—The *British Astronomical Journal*, No. 266, contains two contributions from Mr. S. Yendell and Prof. Dunér, the former "On some observed minima of Y Cygni," and the latter "On the chief cause of the anomalies in the light-variations of Y Cygni." Mr. Yendell in his paper thoroughly agrees with the explanation put forward by Prof. Dunér to account for the anomalies in the light-variations, and says that, when the two series of observations are taken simultaneously, "the substantial correctness of his (Dunér's) fundamental assumption appears to me to be proved beyond the possibility of a cavil." It may be remembered that, in Prof. Dunér's former paper on this subject, he was struck with the discordance of some of Mr. Yendell's observations, which did not seem to harmonize with his own suggested explanation. These observations are now published in detail in this paper, and will be read with interest by those who are following up this curious variable.

Prof. Dunér, in a few words, discusses the results obtained when his own observations are compared with those of Mr. Yendell. The differences between the observed and calculated times of minima showed a decided rate of change, the mean rate being −0·023d., but lacked regularity. In one case the jump from one epoch to another amounted to a rate of − 0·056d., but he thinks that this may be accounted for by a variation in Mr. Yendell's method of observing, for other observations show altogether nearly constant deviations; indeed, "it will be more correct to attribute the discordance simply to errors of observation, than to anomalies in the light-variations of the star."

Active Lunar Volcanoes?—Prof. Pickering, in the *Observatory* for this month, raises the question of active lunar volcanoes, from some recent observations made with the 13-inch Clark, using powers varying from 800–1200. Examining first the Mare Serenitatis, of 67 craters 32 were found common to both charts, 24 on Neison's and not on Prof. Pickering's, while 11 were found on Prof. Pickering's and not recorded by Neison. With higher powers, all Neison's, except two, were discovered, and, in addition, several other small ones. Just about the region of Bessel a change seems to have taken place since Neison made his map, for there are one or two cases in which the crater-pits picked out by him for reference are now not the most conspicuous objects, there being several others far more prominent in the immediate vicinity. The floor of Plato also has been carefully scrutinized, and several of what were then more or less distinct luminous points are now either invisible or barely so, while one large crater was seen where previously none was recorded. Whether a real change has taken place in these parts of the moon's surface, or whether the antecedent observations were sufficiently accurate, is a matter of doubt, and it is for future observers to determine this. But now, as Prof. Pickering says, "that we are able to study the smaller lunar craters to advantage, and so many changes are noted, it does not seem as if the same cause (the mere action of sunlight) can have affected so many of them in the same way, nor does it seem as if all the changes noted can be due to erroneous delineation."

CATALOGUE OF NEBULÆ.—In *Astronomische Nachrichten*, No. 3094, the Catalogue No. 10 of nebulæ discovered at the Warner Observatory by Swift is inserted. The number included, which generally consists of one hundred, amounts here to sixty, the reason being that owing to the increasing number of electric street lights these faint objects are rendered invisible by the illumination of the atmosphere.

GEOGRAPHICAL NOTES.

DR. HENRY SCHLICHTER contributes a valuable epitome of our knowledge of the pygmies of Africa to the June number of the *Scottish Geographical Magazine*. He divides the dwarf tribes hitherto reported into four great groups, according to the regions they inhabit, recognizing, however, the probability of further exploration revealing connecting links between them. The first group, or dwarfs of West Africa, includes the Obongo, Akoa, and Babongo, which vary between 4 and 5 feet in height. The second, or Central African group, contains the Akka, Wambutti, and Batua, of even smaller stature, inhabiting the Congo Basin, scattered amongst Bantu tribes. The third group is that of the East African pygmies, whose existence east of the Nile and south of Kaffa was reported as early as 1826; but they are still little known. The fourth group, those dwelling south of the Congo basin, is relegated to another paper.

ORDNANCE MAPS of Great Britain are at last coming prominently before the public. Although not likely to gratify those engaged in producing the sheets, popular attention will doubtless result in direct and early benefit to cartography and even to geography at large. A Parliamentary Committee, on which scientific geographers are well represented, has the whole matter under investigation, and the energetic criticisms of Mr. Crook, which have so long passed unheeded, are now receiving further expression in a series of articles in the *Times*. The particular object of attack is the new quarter-inch outline map of England and Wales, a map put forward by the Survey with some natural diffidence, for it is founded on measurements the most recent of which were made twenty years ago, and the earliest at the very beginning of the century. The delineation of the country, in consequence of the want of subsequent revision, resembles a star-chart, in so far as it represents each point as it existed at some different time in the past. Unlike a star-chart, however, the quarter-inch map of England is of no scientific and little practical value. The more thoroughly this matter is investigated, and the more speedily it is rectified, the better will it be for the Survey officers, whose magnificent triangulations and unparalleled accuracy of observation have made the mapping of the British Islands a model for the world to admire. It is high time that steps be taken for regular periodical revision of all Ordnance maps, and for publication in a form comparable with that of the Staff maps of France and other Continental nations.

AN appreciative article on the late Prof. Freeman and his services to geography appears in the June number of the *Proceedings* of the Royal Geographical Society. Freeman's most important service was to demonstrate that the physical geography of a region largely determines the political geography of the countries upon it, and that a knowledge of past geographical conditions is essential in order to understand history.

THE report of an expedition to Argentine Tierra del Fuego by Señor Julio Popper has been recently published by the Argentine Geographical Society. The region in question is the eastern half of Tierra del Fuego, the geological structure of which is mainly Tertiary rocks much disintegrated; the coast line is little indented, with few harbours, the sea shallow and abounding in sand-banks, while the climate, dominated by the warm Brazil current, is equable and moist. The south coast bordering the Beagle Channel is rugged, rocky, and under the climatic influence of the cold Antarctic drift. The tribes inhabiting the island of Tierra del Fuego proper are the Ona (compare NATURE, xlv. 577), who are described as of fine physique, resembling the Indians of North America, and susceptible of civilization. Indeed, Señor Popper contrasts their magnanimous and forgiving character very favourably with the unreasoning cruelty of the white gold-seekers who have invaded their territory, yet the Onas are said to be inveterate thieves. The map accompanying this report is covered with new names for features already designated, and it can hardly be expected that these will be accepted by European geographers.

MRS. BISHOP (Miss Bird) read an interesting paper on her recent journey to Little Tibet, before the London branch of the Royal Scottish Geographical Society, on May 31, the Duke of Argyll presiding. Lady travellers are not encouraged to describe their expeditions to the Royal Geographical Society, and as the British Association, which receives communications from men and women on an equal footing, cannot meet in London, this opportunity for a metropolitan audience to hear at first hand the account of an adventurous journey, and the sympathetic estimate of the inhabitants of a little-known region, by a woman of Mrs. Bishop's tried courage and trained observing powers was naturally taken advantage of to the utmost.

MICRO-ORGANISMS IN THEIR RELATION TO CHEMICAL CHANGE.[1]

ALMOST exactly on this day twenty-two years ago the subject of micro-organisms was introduced to the audience of the Royal Institution in one of those charming discourses, which so many of us well know were always to be heard from Dr. Tyndall. The title of his discourse on that occasion was "Dust and Disease," and its contents should be studied by all interested in this departure of science, forming, as it does, a part of the classical literature of the subject in which it marks the commencement of a new epoch.

It has probably rarely, if ever, happened before, that in so short a period as twenty-two years any science has undergone such a marvellous advance, such a many-sided development, as that which has taken place in the case of bacteriology, the science which is devoted to the study of those low forms of life which we group together under the name of *micro organisms*. This advance has been made through the ungrudging expenditure of self-denying labour by a great body of earnest workers of nearly every nationality. The subject is, indeed, one calculated to draw forth interest and enthusiasm, for the problems involved are not only of high scientific importance, but are also of incalculable moment to mankind, and, indeed, to the entire living creation.

The great impetus which this new science received at its outset was imparted by Pasteur, who has not only laid the foundations, but has also added, and is still adding, so much to the superstructure of its many mansions.

The side of bacteriology with which the general public is most commonly brought in contact is that which relates to disease, but of this I propose saying absolutely nothing to-night. It has been dealt with by others in this place, and notably by my friend Dr. Klein.

There is a second side of bacteriology which has also a special interest for at least a portion of the public, in consequence of the invaluable assistance which it has afforded to some sections of the industrial world. Indeed, chronologically, this industrial department of bacteriology was the first which claimed attention, for the growers of wine, the brewers of beer, and the manufacturers of fermented liquors of all kinds from the highest antiquity have been practical bacteriologists, of the same spontaneous order, it is true, as M. Jourdain was an unconscious author of prose. It was Pasteur also who first infused science into the operations of the wine-vat and the fermenting-tun, by his classical "Études sur la Bière et sur le Vin." It was he who first showed that the normal work of the brewery was accomplished by particular forms of micro-organisms, known as yeast, and that the frequent failures to produce beer or wine of the desired quality was occasioned by the presence of foreign forms of micro-organisms giving rise to acidity and other undesirable changes in these beverages.

---

[1] Friday Evening Discourse, delivered by Prof. Percy F. Frankland F.R.S., at the Royal Institution of Great Britain, on February 19, 1892.

In these researches of Pasteur's on beer and wine, we are almost for the first time brought face to face with the precise nature of some of the chemical changes which micro-organisms bring about. The time-honoured vinous fermentation of sugar, the products of which had been valued and indulged in by man even from the days of Noah, is for the first time so accurately studied as to be definable almost with the precision of a chemical equation.

Similar attention was also given by Pasteur to some of the other micro-organisms which deteriorate the quality of the beer—thus more especially to the bacterium which causes the *acetic* or vinegar fermentation, which is a process of *oxidation*, transforming alcohol into vinegar; to the bacillus inducing the *lactic* fermentation, which is a process of *decomposition*, in which sugar yields lactic acid; as well as to that which brings about the *butyric* fermentation, a process of *reduction*, in which butyric acid is formed.

These are the foundations and scaffolding on which subsequent investigators of the phenomena of fermentation have laboured. Thus, making use of more refined methods than those which were at the disposal of Pasteur, Christian Hansen, of Copenhagen, has enormously extended our knowledge of the alcohol-producing organisms or yeasts; he has shown that there are a number of distinct forms, differing indeed but little amongst themselves in shape, but possessing very distinct properties, more especially in respect of the nature of certain minute quantities of secondary products to which they give rise, and which are highly important as giving particular characters to the beers produced. Hansen has shown how these various kinds of yeast may be grown or cultivated in a state of purity even on the industrial scale, and has in this manner revolutionized the practice of brewing on the Continent. For during the past few years these pure yeasts, each endowed with particular qualities, have been grown with scrupulous care in laboratories equipped expressly for this purpose, and these pure growths are thence despatched to breweries in all parts of the world, particular yeasts being provided for the production of particular varieties of beer. In this manner scientific accuracy and the certainty of success are introduced into an industry in which before much was a matter of chance, and in which nearly everything was subordinated to tradition and blind empiricism.

The Bacteria connected with the Soil.

It is, however, with regard to the bacteria connected with other industries than those of alcoholic fermentation that our knowledge has particularly advanced during the last few years. Thus some of the most important phenomena in agriculture have recently received a most remarkable elucidation through the study of bacteria.

Scientific agriculturists are generally agreed that one of the most important plant-foods in the soil is *nitric acid;* indeed they inform us that if a soil were utterly destitute of this material it would be incapable of growing the barest pretence of a crop, *either of corn, or of roots, or of grass*, even if the soil were in other respects of the most superb texture, however favourably it might be situated, however well drained, tilled, and supplied with the purely mineral ingredients of plant-food, such as *potash*, *lime*, and *phosphoric acid*.

Yet, notwithstanding the commanding importance of this substance nitric acid to vegetation, it is present in ordinary fertile soils in but little more than homœopathic doses.

These facts are gathered from those grand experiments which have during the past half-century been going on at Rothamsted under the direction of Sir John Lawes and Dr. Gilbert, and which have rendered the Hertfordshire farm a luminous centre of the whole agricultural world.

From these experiments it appears that sometimes there is in fertile soil under 1 part, and often under 10 parts, of nitrogen as nitrate per million of soil.

Indeed, in order to detect and estimate these minute quantities, the most refined methods of chemical analysis have to be called into requisition. [Demonstration of the presence of nitric acid in soil by diphenylamine test.]

Now the cause of such minute quantities only of nitric acid being found in soils is due partly to this material being washed away by the rain, and partly to its being so eagerly taken up by plants for the purposes of nutrition; for it has long been known that by suitable means the quantity can be enormously increased if no vegetation is maintained, and the ground properly protected from rain. The soil, in fact, under ordinary circumstances, continuously generates this nitric acid from the various nitrogenous manures which are applied to it, and it is in the form of nitric acid that the nitrogen of manures principally gains access as nutriment to the plant.

It was in the year 1877 that two French chemists, Schlœsing and Müntz, showed that this power of soils to convert the nitrogen of nitrogenous substances into nitric acid was due to low forms of life—to micro-organisms or bacteria. The proof which they furnished of this statement was of a very simple character, and consisted essentially in demonstrating that this production of nitric acid, or process of *nitrification*, as it is generally called, is promptly inhibited or brought to a standstill by all those materials which have the property of destroying micro-organisms, and which we call *antiseptics;* whilst similarly the process is stopped by heat and other influences which are known to be fatal to life in general.

These results of Schlœsing and Müntz were confirmed and greatly extended in this country by Mr. Warington and Dr. Munro, but although the vital nature of the process was fully established, little practical advance was until recently made in the identification or isolation of the particular bacteria responsible for this remarkable and invaluable transformation.

In 1886, however, a very important step was made by Dr. Munro, who showed that this process of nitrification could take place in solutions practically destitute of organic matter, or, in other words, that the vital activity of the bacteria of nitrification could be maintained without nutriment of an organic nature.

In 1885, I had myself already established the fact that some micro-organisms can actually undergo enormous multiplication in ordinary distilled water:—

Multiplication of Micro-organisms in Distilled Water.[1]

Hours after introduction of micro-organisms.	Number of micro-organisms found in 1 c.c. of water.
0	1,073
6	6,028
24	7,262
48	48,100

In taking up the subject of nitrification in conjunction with my wife in the autumn of 1886, I determined to avail myself of this remarkable property of the nitrifying organisms to grow in the absence of organic matter, thinking that in this way it would be possible to achieve a separation of the nitrifying organisms from other forms which can only grow if organic food materials are supplied to them.

Proceeding on these lines, we have carried on the process of nitrification over a period of upwards of four years without the nitrifying organisms being supplied with any organic food materials whatsoever:—

Composition of Solution employed for Nitrification.

Ammonium chloride	·5 grm.	In 1000 c.c. of distilled water.
Potassium phosphate	·1 ,,	
Magnesium sulphate	·02 ,,	
Calcium chloride	·01 ,,	
Calcium carbonate	5·0 ,,	

In a solution of this composition the process of nitrification was carried on over a period of upwards of four years, as indicated in the table on p. 137.

In carrying on this series of experiments it was soon evident that although a number of forms foreign to the nitrification process were being eliminated, there were still some remaining alongside of the nitrifying organisms, or, in other words, that a pure culture of the nitrifying organisms had not been obtained. From various considerations, however, we came to the conclusion that the nitrifying organisms probably differed from the other forms which were still present along with them in being unable to grow on the common cultivating medium employed by bacteriologists, and known as gelatin-peptone.

---

XXVIII.	3 3 1891	,, XXVII.	28 5 1891

The separation from these foreign forms was ultimately effected by enormously diluting one of these nitrifying solutions, and then taking out small portions of this diluted material and introducing each of these portions into separate ammoniacal solutions. In some of these nitrification was established, in others not, whilst amongst those in which nitrification *was* established, some contained organisms which grew upon gelatin, whilst one refused to give any growth on the gelatin at all, although it was seen under the microscope to contain abundantly bacteria of the form shown in the diagram. [Lantern-slide of nitrifying bacillococcus (Frankland).]

These results, which were published in March 1890, were followed in about a month by a communication in the *Annales de l'Institut Pasteur*, by M. Winogradsky, who had also separated a very similar, if not identical, nitrifying organism, and a few months later again a similar separation was made by Mr. Warington.

But these discoveries had not completely unravelled the problem of nitrification, for the organisms separated in these three independent investigations possessed only the property of *converting ammonia into nitrous and not into nitric acid.* The nitrous acid is an intermediate body, which curiously is rarely found excepting in very minute quantities in soil. The changes will be more clearly understood by reference to the chemical equations:—

$$(1)\quad \underset{\text{(Ammonia)}}{NH_3} + \underset{\text{(Oxygen)}}{3O} = \underset{\text{(Water)}}{H_2O} + \underset{\text{(Nitrous Acid)}}{NHO_2}$$

$$(2)\quad \underset{\text{(Nitrous Acid)}}{NHO_2} + O = \underset{\text{(Nitric Acid)}}{NHO_3}$$

The organisms separated by Winogradsky, by Warington, and by myself, possessed only the property of effecting the first of these changes, they were absolutely destitute of the power of bringing about the second.

Now, the curious thing is that the first of these changes is by far the most difficult to accomplish by *purely chemical means*, whilst the second can be brought about with the greatest facility. [Demonstration of addition of acid permanganate to solution of ammonium sulphate, colour not discharged.] [Demonstration of addition of acid permanganate to solution of potassium nitrite, colour discharged.]

Thus the potassium permanganate has no action on the ammonia, whilst the nitrite it oxidizes to nitrate.

In order to bring about the first change, we have to employ one of the most powerful oxidizing agents known to chemists, viz. ozone. [Demonstration: ozone from a Siemens tube was passed through strong solution of ammonia; the production of nitrous and nitric acids was exhibited by the formation of white fumes, as well as by the sulphanilic acid and diphenylamine tests.]

We thus see that the power of oxidation possessed by our nitrifying organism is altogether unique, and does not find its parallel amongst purely chemical agents of oxidation. *But how then is the nitric acid found in the soil produced, when these organisms yield only nitrous acid?*

At the time when I found that the organism which I had separated produced nitrous acid exclusively, I pointed out that it was doubtless explicable on one of two hypotheses: (1) that nitrous and nitric acids are produced by totally distinct organisms; or (2) that the same organism produces the one or the other according to the conditions under which it is growing.

More recent researches of Winogradsky have shown that the first of these two alternative hypotheses is the correct one, for, by making cultivations of soil in a solution containing nitrous acid and no ammonia, Winogradsky has succeeded in isolating a micro-organism which possesses the power of converting nitrous acid into nitric acid, but has no power of attacking ammonia. [Lantern-slide of nitric ferment (Winogradsky).]

This second organism or *nitric ferment*, as we may call it, resembles in its activity the purely chemical oxidizing agent—*potassium permanganate*—which, as we have seen, has no action on ammonia, but readily converts nitrous into nitric acid.

The process of nitrification in the soil now becomes intelligible in its entirety. It is the work of two independent organisms, the first of which converts ammonia into nitrous acid, whilst the second transforms into nitric acid the nitrous acid produced by the first.

There is a point in connection with the distribution of nitric acid in nature which is exceedingly remarkable, and which forces itself upon the attention of every student of the process of nitrification. Although nitric acid is generally so scantily present in the soil, there is one notable exception to this rule, for in the rainless districts of Chili and Peru there are found immense deposits of nitrate of soda, or Chili-saltpetre, as it is called, which would appear to represent the result of a gigantic nitrification process in some previous period of the earth's history. The vast quantities of this material which occur in these regions of South America can be gathered from the fact that its exportation has for years been going on at the rate indicated by the following figures:—During the first six months of 1890 there were brought to the United Kingdom 90,000 tons, and to the European continent 480,000 tons.

From the presence of such altogether enormous quantities, one is almost tempted to hazard the suggestion that in this particular region of the earth, under some special circumstances of which we know nothing, the nitrifying organisms must have been endowed then and there with very much greater powers than they possess to-day, and it is particularly noteworthy that in a recent examination of soils from nearly all parts of the earth, one coming from Quito, and therefore not far distant from these nitrate fields, was found to possess the power of nitrification in a degree far beyond that exhibited by any other soil hitherto experimented with. Is it not possible, perhaps, that we have in these vigorous nitrifying organisms of the soil of Quito, the not altogether unworthy descendants of the Cyclopean race of nitrifying bacteria, which must have built up the nitrate wealth of Chili and Peru, and thus countless ages ago founded the fortunes of our nitrate kings of to-day?

But these nitrifying organisms have also assisted in teaching us a highly important lesson in connection with the maintenance of life.

The facts which I have already referred to concerning the multiplication of micro-organisms in distilled water, and the continuation of the nitrification-process over a period of four years in purely mineral solutions, are strong presumptive evidence in favour of these bacteria being able to gain a livelihood in the entire absence of organic food-stuffs. I refrained, however, from promulgating such a revolutionary doctrine until I should have had an opportunity of repeating these experiments with materials in which the absence of even the merest traces of organic matter had been assured, for, as chemists well know, even distilled water may contain traces of organic matter.

Such a rigid proof as I had contemplated has, however, in the meantime been attempted by M. Winogradsky, also in connection with his experiments on nitrification, and he has indeed found that the nitrifying organisms flourish, multiply, and actually build up living protoplasm in a solution from which organic matter has been most rigorously excluded. Now this living protoplasm in the experiments in question must have been elaborated by these bacteria from carbonic acid as the source of the protoplasmic carbon, and from ammonia and nitrous or nitric acids as the source of the protoplasmic nitrogen. If these experiments are correct, and they were undoubtedly performed with great skill and much caution, they are subversive of one of the fundamental principles of vegetable physiology, which denies to all living structures, save those of green plants alone, the power of building up protoplasm from such simple materials.

I had occasion to mention in connection with these nitrifying organisms that they refuse to grow on the ordinary solid cultivating media employed by bacteriologists, a fact which presents a great obstacle to their isolation in a state of purity, for it is just by means of these solid culture media that micro-organisms are most easily obtained in the pure state.

This difficulty has, however, been overcome in a most ingenious manner, originally devised by Prof. Kühne, in which the solid medium is wholly composed of mineral ingredients, the jelly-like consistency being obtained by means of silica. [Demonstration of preparation of silica-jelly, consisting of ammonia sulphate, potassium phosphate, magnesium sulphate, calcium chloride, magnesium carbonate, and dialyzed silicic acid.]

Fixation of Free Nitrogen by Plants.

But whilst the study of the bacteria giving rise to nitrification has thus led to the subversion of what was regarded as a firmly established principle of vegetable physiology (viz. *the incapacity of any but green plants to utilize carbonic acid in the elaboration of protoplasm*), the same science has received another shock, of perhaps equal if not greater violence, through researches which have been carried on with other micro-organisms flourishing in the soil.

For nearly a century past agricultural chemists and vegetable physiologists have been debating as to whether the free nitrogen of our atmosphere can be assimilated or utilized as food by plants. This question was answered in the negative by Boussingault about fifty years since; the problem was again attacked by Lawes, Gilbert, and Pugh about thirty years ago, and *their* answer was also in the negative. In the course, however, of their continuous experiments on crops, Lawes and Gilbert have frequently pointed out that whilst the nitrogen in most crops can be accounted for by the combined nitrogen supplied to the land in the form of manures and in rain water, yet in particular *leguminous* crops, such as peas, beans, vetches, and the like, there is an excess of nitrogen which cannot be accounted for as being derived from these obvious sources. The origin of this excess of nitrogen in these particular crops they admitted could not be explained by any of the orthodox canons of the vegetable physiology of the time. The whole question of the fixation of atmospheric nitrogen by plants was again raised in 1876 by a very radical philosopher, in the person of M. Berthelot, whilst the most conclusive experiments were made on this subject by two German investigators, Prof. Hellriegel and Dr. Wilfarth, who have not only shown that this excess of nitrogen in leguminous crops is obtained from the atmosphere, but also that this assimilation of free nitrogen is dependent upon the presence of certain bacteria flourishing in and around the roots of these plants, for when these same plants are cultivated in sterile soil the fixation of atmospheric nitrogen does not take place. Moreover, the presence of these microbes in the soil occasions the formation of peculiar swellings or tuberosities on the roots of these plants, and these tuberosities, which are not formed in sterile soil, are found to be remarkably rich in nitrogen, and swarming with bacteria. [Lantern-slide of nodules on roots of sainfoin (Lawes and Gilbert).]

Extremely important and instructive in this respect are the experiments of Prof. Nobbe, who has not only confirmed the results mentioned, but has endeavoured to investigate the particular bacteria which bring about these important changes, and he has indeed succeeded in showing that in many cases each particular leguminous plant is provided with its particular micro-organism which leads to its fixation of free nitrogen. Thus he found that if pure cultivations of the bacteria obtained from a pea-tubercle were applied to a pea plant there was a more abundant fixation of atmospheric nitrogen by this pea-plant than if it was supplied with pure cultures of the microbes from the tubercles of a lupin or a robinia; whilst similarly the robinia was more beneficially affected by the application of pure cultures from robinia-tubercles than by those from either pea-tubercles or lupin-tubercles. [Lantern-slides exhibiting Nobbe's experiments on pea and robinia.]

This subject of the source of nitrogen in leguminous plants has again been taken up by Sir John Lawes and Dr. Gilbert at Rothamsted, and their recent results fully confirm the observations of these foreign investigators that it is partially derived from the free atmospheric nitrogen through the agency of bacteria in the soil.

To micro-organisms again, then, we must ascribe the accomplishment of this highly important chemical change going on in the soil, although it has not hitherto been so fully illuminated as the process of nitrification.

Selective Action of Micro-organisms.

Any of the ordinary plants and animals with which we are familiar may be regarded as analytical machines, and we ourselves, without any knowledge of chemistry, are constantly performing analytical tests; thus we can all distinguish between sugar and salt by the taste, between ammonia and vinegar by the smell, whilst by a more elaborate investigation we distinguish, for instance, between the milk supplied from two different dairies by ascertaining on which we or our children thrive best. In fact, such analytical or selective operations are amongst the first vital phenomena exhibited by an organism on coming into this world. It is, however, particularly surprising to find this analytic or distinguishing capacity developed in an extraordinarily high degree amongst micro-organisms. From the power which we have seen that some possess of flourishing on the extremely thin diet to be found in distilled water, we should be rather disposed to think that caprice would be the very last failing with which they would be chargeable. As a matter of fact, however, the perfectly unfathomable and inscrutable caprice of these minute creatures is amongst the first things with which the student of bacteriological phenomena becomes impressed. Let me call your attention to a striking example of this which I have recently investigated.

I have here two substances, which have the greatest similarity:—

	MANNITE.	DULCITE.
Occurrence.	Numerous plant-juices ...	Ditto, but less frequently.
Taste.	Sweet	Ditto, but less so.
Melts.	166° C.	188° C.
Crystalline form.	Large rhombic prisms	Large monoclinic prisms.

Not only, however, do these two substances possess such a strong external resemblance to each other, but in their chemical behaviour also they are so closely allied that one formula has to do duty for both of them, for so slight is the difference in the manner in which their component atoms are arranged that chemists have not yet been able with certainty to ascertain in what that difference consists. Under these circumstances it would have been anticipated that bacteria would be quite indifferent as to which of these two substances was presented to them, and that they would regard either both or neither as acceptable. But such is by no means the case; some micro-organisms, like ordinary yeast, have *no action upon either*, whilst *others will attack mannite, leaving dulcite untouched, others again, being less discriminating, attack both;* representatives of a fourth possible class *which would act upon dulcite but not upon mannite* are as yet undiscovered. [Lantern-slide and plate-culture of *B. ethaceticus.*]

This bacillus, I have recently shown, has the property of breaking down the mannite molecule into alcohol, acetic acid, carbonic anhydride, and hydrogen, but leaves the dulcite molecule untouched.

More recently I have, in conjunction with my late assistant, Mr. Frew, succeeded in obtaining a micro-organism which decomposes both mannite and dulcite into alcohol, acetic and succinic acids, carbonic anhydride, and hydrogen. [Lantern-slide and plate-culture of *B. ethacetosuccinicus.*]

Optically Active Substances.

But these are by no means the ultimate limits to which the selective or discriminating powers of micro-organisms can be pushed, for although mannite and dulcite are extremely similar substances, they are not chemically identical. We are acquainted, however, with substances which, though chemically identical, are different in respect of certain physical properties, and are hence known as *physical isomers*. It is in explanation of this physical isomerism that one of the most beautiful of chemical theories was propounded by Lebel and Van 't Hoff in 1874, and which remains unsupplanted to the present day.

This theory depends upon taking into consideration the dissymmetry of the molecule which is occasioned by the presence in it of a carbon-atom which is combined with four different atoms or groups of atoms, and is most easily intelligible from an inspection of these two models. [Demonstration of tetrahedral models of asymmetric carbon-atom.]

This molecular dissymmetry is specially exhibited in the crystalline form of such substances, and in their action upon polarized light.

The molecule arranged according to the one pattern has the property of turning the plane of polarization in one direction, whilst the molecule arranged according to the other pattern has invariably the property of turning the plane through precisely the same angle in the opposite direction. The molecular dissymmetry ceases when two such molecules combine together, the resulting molecule having no action on polarized light at all.

The interest of these phenomena in connection with micro-organisms lies in the fact that they are sometimes possessed of the power of discriminating between these physical isomers. Although this remarkable property was demonstrated years ago by Pasteur in respect of the tartaric acids, it has only comparatively rarely been taken advantage of. Recently, however, chemical science has been enriched in several instances by successfully directing the energies of micro-organisms in such work of discrimination.

During the past few years no chemical researches have commanded more interest, both on account of their theoretic importance and the fertility of resource exhibited in their execution, than those of Emil Fischer's, which have led to the artificial preparation in the laboratory of several of the various forms of sugar occurring in nature, as well as of other sugars not hitherto discovered amongst the products of the animal or vegetable kingdoms. The natural sugars are all of them bodies with dissymmetric molecules, powerfully affecting the beam of polarized light, but when prepared artificially they are without action on polarized light, because in the artificial product the left-handed and right-handed molecules are present in equal numbers, the molecules of the one neutralizing the molecules of the other, and thus giving rise to a mixture which does not affect the polarized beam either way. By the action of micro-organisms, however, on such an inactive mixture, the one set of molecules is searched out by the microbes and decomposed, leaving the other set of molecules untouched, and the latter now exhibit their specific action on polarized light, an active sugar being thus obtained.

The most suitable micro-organisms to let loose, so to speak, on such an inactive mixture of sugar-molecules, are those of brewers' yeast, which decompose the sugar molecules with formation of alcohol and carbonic anhydride. Their action on these inactive artificial sugars of Fischer's is particularly noteworthy.

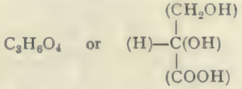
One of the principal artificial sugars prepared by Fischer is called *fructose*; it is inactive, but consists of an equal number of molecules of oppositely active sugars called *lævulose*.

One set of these lævulose-molecules turns the plane of polarization to the right, and we may call them *right-handed lævulose*, whilst the other set of *lævulose-molecules* turns the plane of polarization to the left, and we may call them *left-handed lævulose*.

The left-handed lævulose occurs in nature, whilst the right-handed lævulose, as far as we know, does not. Now, on putting brewers' yeast into a solution of the fructose, the yeast-organisms attack the left-handed lævulose molecules and convert them into alcohol and carbonic anhydride, whilst the right-handed lævulose is left undisturbed. The yeast organisms thus attack that particular form of lævulose of which their ancestors can have had experience in the past, whilst they leave untouched the right-handed lævulose molecules, which, being a new creation of the laboratory, they have no hereditary instinct or capacity to deal with.

This selective power is possessed also by other forms of micro-organisms besides the yeasts, which are indeed only suitable for the separatory decomposition of sugars, and by means of bacterial forms a much greater variety of substances can be attacked in this manner. Thus I have recently found that glyceric acid can be decomposed by the *B. ethaceticus*, to which I have already referred this evening.

This glyceric acid is thus represented by chemists:—



$$C_3H_6O_4 \quad \text{or} \quad \begin{array}{c} (CH_2OH) \\ | \\ (H)\text{—}C(OH) \\ | \\ (COOH) \end{array}$$

and this should, according to Le Bel and Van 't Hoff's theory, be capable of existing in two physically isomeric forms, as easily shown by our models.

The ordinary glyceric acid known to chemists is, however, quite inactive to polarized light, and must consist, therefore, of a combination in equal molecules of a right-handed and left-handed glyceric acid. Now when the *B. ethaceticus* is put into a suitable solution of the calcium salt of this glyceric acid, it multiplies abundantly, and completely consumes the right-handed molecules of the salt, but leaves the left-handed molecules entirely intact, a powerfully active glyceric acid being thus obtained. [Demonstration of the lævorotary power of solution of new zinc glycerate with projection-polariscope.]

A number of derivatives of this new active glyceric acid have recently been prepared in my laboratory:—

Derivatives of Active Glyceric Acid.

Formula.	Specific Rotation. $[\alpha]_D$
$(C_3H_5O_3)_2$ Ba + $2H_2O$	− 9°
$(C_3H_5O_3)_2$ Sr + $3H_2O$	− 10
$(C_3H_5O_3)_2$ Ca + $2H_2O$	− 12
$(C_3H_5O_3)_2$ Cd + $1\frac{1}{2}H_2O$	− 14
$(C_3H_5O_3)_2$ Zn + H_2O	− 22
$(C_3H_5O_3)_2$ Mg + H_2O	− 18·5
$C_3H_5O_3$ Na	− 16
$C_3H_5O_3$ Am	− 20
$C_3H_5O_3$ K	− 15

$C_3H_5O_3$ Me	− 4·8
$C_3H_5O_3$ Et	− 9·2
$C_3H_5O_3$ Pr (*n*)	− 13·0

Here again, then, chemistry has been enriched by a number of new compounds, which we owe entirely to the unaccountable caprice of this micro-organism.

Individuality of Micro-organisms.

Although micro-organisms are thus becoming more and more indispensable reagents in the chemical laboratory, essential as they are for the production of many bodies, it is always necessary to bear in mind that by virtue of their vitality their nature is infinitely more complex than that of any inanimate chemicals which we are accustomed to employ. In a chemically pure substance we believe that one molecule is just like another, and hence we expect perfect uniformity of behaviour in the molecules of such a pure substance under prescribed conditions. In a pure cultivation of a particular species of micro-organism, however, we must not expect such rigid uniformity of behaviour from each of the individual organisms making up such a cultivation, for there may be and frequently are great differences amongst them; in fact, each member of such a pure culture is endowed with a more or less marked individuality of its own, and these possible variations have to be taken into consideration by those who wish to turn their energies to account. In fact, experimenting with micro-organisms partakes rather of the nature of legislating for a community than of directing the inanimate energies of chemical molecules. Thus frequently the past history of a group of micro-organisms has to be taken into account in dealing with them, for their tendencies may have become greatly modified by the experiences of their ancestors.

Of this I will give you an instance which has recently come under my observation:—

Here is a bacillus, which has the property of fermenting calcium citrate; I have found that it can go on exerting this power for years. On submitting this fermenting liquid to plate-cultivation, we obtain the appearances which you see here. [Lantern-demonstration of plate-culture of bacillus which ferments calcium citrate.]

If one of these colonies be transferred to a sterile solution of calcium citrate, it invariably fails to set up a fermentation of the latter, the bacillus having thus by mere passage through the gelatin-medium lost its power to produce this effect. If, however, we take another similar colony and put it into a solution of broth containing calcium citrate, fermentation takes place; on now inoculating from this to a weaker solution of broth containing calcium citrate, this also is put into fermentation, and by proceeding in this manner we may ultimately set up fermentation in a calcium citrate solution which absolutely refused to be fermented when the bacilli were taken directly from the gelatin-plate.

Phenomena of this kind clearly indicate that there may be around us numerous forms of micro-organisms of the potentiality of which we are still quite ignorant. Thus, if we were only acquainted with the bacilli I have just referred to from gelatin cultures, we should be quite unaware of their power to excite this fermentation of calcium citrate, which we have only been enabled to bring about by pursuing the complicated system of cultivation I have indicated. It is surely exceedingly probable, therefore, that many of the micro-organisms with which we are already acquainted may be possessed of numerous important properties which are lying dormant until brought into activity by suitable cultivation.

This power of modifying the characters of bacteria by cultivation is, I venture to think, of the highest importance in connection with the problems of evolution, for in these lowly forms of life, in which, under favourable circumstances, generation succeeds generation in a period of as little as 20 minutes, it should be possible through the agency of selection to effect metamorphoses, both of morphology and physiology, which would take ages in the case of more highly organized beings to bring about.

We hear much about the possibility of altering the human race through training from the enthusiastic apostles of education, but even the most sanguine cannot promise that any striking changes will be effected within several generations, so that such predictions cannot be tested until long after these reformers have passed away. In the case of micro-organisms, however, we can study the effect of educational systems consequentially pursued through thousands of generations within even that short span of life which is allotted to us here.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. Peile, Master of Christ's College, has been re-elected Vice-Chancellor for the ensuing academical year.

The examination for the Diploma in Public Health will begin on October 4. Candidates are to send their names to the Registrary by September 27.

Prof. Roy announces a special course in Bacteriology, to be given during the long vacation by Mr. Adami, Mr. Kanthack (one of the Leprosy Commissioners), and Dr. Lloyd Jones, beginning on July 8. It is especially intended for candidates, not necessarily members of the University, for the Diploma in Public Health.

An elaborate scheme for the proposed Mechanical Sciences Tripos has been prepared by a special Syndicate, and appears in the *University Reporter* for May 31. The Tripos follows the main lines of the Natural Sciences Tripos, and seems to be free from the objections which have proved fatal to former schemes.

It is understood that the persons on whom honorary degrees are to be conferred on June 11, in connection with the Chancellor's inauguration, have been for the most part nominated by his Grace. This will perhaps account for the political character of the list, which is, however, partially relieved by the presence on it of General R. Strachey, and Mr. G. W. Hill, late of the office of the *American Ephemeris*, and known among astronomers for his fine work on the lunar theory. Five of the honorary graduates are Fellows of the Royal Society.

The University College of Wales, Aberystwyth, has been admitted to the privileges of a College affiliated to the University. The Mason College of Science, Birmingham, has been associated with the Local Lectures Syndicate in the work of University Extension.

Dr. W. Howship Dickinson, Dr. Bradbury, and Dr. J. F. Payne have been appointed Examiners in Medicine, Dr. W. S. Playfair and Dr. Griffith Examiners in Midwifery, and Messrs. Herbert Page, Frederick Treves, and Howard Marsh Examiners in Surgery.

Notice of opposition to the appointment of Sir R. S. Ball to the Directorship of the Observatory has been given. The grounds stated are that the duties of the Professorship of Geometry and Astronomy should occupy the whole time of the Professor, while the energies of the Director, in view of the recent developments of astronomical science, should be entirely devoted to the work of the Observatory. It is also held to be unwise in these circumstances to refuse the munificent offer of Mrs. Adams to provide £10,000 for the endowment of a separate Director.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 19.—"On the Changes produced by Magnetization in the Length of Iron and other Wires carrying Currents." By Shelford Bidwell, M.A., LL.B., F.R.S.

The changes of length attending the magnetization of rods or wires of iron and other magnetic metals which were first noticed by Joule in 1841, and have in recent years formed the subject of many experiments by the author, have been found to be related to several other phenomena of magnetism. Maxwell has suggested that they sufficiently account for the twist which is produced in an iron wire when magnetized circularly and longitudinally at the same time. The resultant lines of magnetization, as he points out, take a spiral form; the iron expands in the direction of the lines of magnetization, and thus the wire becomes twisted. Prof. G. Wiedemann, however, to whom the discovery of the magnetic twist is due, appears not to be satisfied with this explanation, believing the effect to be caused by unequal molecular friction.

The subject of magnetic twists has been very fully and carefully investigated by Prof. C. G. Knott, and in a paper published last year in the Transactions of the Royal Society of Edinburgh (vol. xxxvi., Part II., p. 485) he indicates many details in which the phenomena of twist closely correspond with those of elongation and retraction. Assuming their essential identity, and noting that "an increased current along the wire affects the points of vanishing twist in a manner opposite to that in which an increased tension affects it," Prof. Knott is "inclined to conclude that the pure strain effects of these influences are of an opposite character." Now, since the magnetic elongation of an iron wire is known to be diminished by tension, the remark above quoted amounts to a prediction that in an iron wire carrying a current the magnetic elongation would be increased. "We know nothing so far," Prof. Knott observes, "regarding the changes of length when an iron wire *carrying a current* is subjected to longitudinal magnetizing forces"; and it was with the object of acquiring some information on this point, and testing Prof. Knott's prediction, that the experiments described in the present paper were undertaken. The results show that it was amply verified, and thus Maxwell's explanation of the twist receives still further corroboration.

The apparatus used and the methods of observation were the same as those described in former papers. Each specimen of wire examined was 10 cm. long, and the indications of the instrument were read to one ten-millionth part of the length.

The wire first used was of soft commercial annealed iron, 0·75 mm. in diameter. The changes of length which it exhibited under the influence of magnetizing forces gradually increased from 13 to 315 C.G.S. units are indicated in the second column of Table I., in which the unit is one-millionth of a centimetre or one ten-millionth of the effective length of the wire.

The experiment described in the last paragraph was repeated while a current of 1 ampere was passing through the wire, the several magnetizing forces employed being made as nearly as possible the same as before by inserting the same resistances successively in the circuit. The results appear in the third column of Table I., and show that the maximum elongation had risen from 11·5 to 14·5 ten-millionths, while the decrement in a field of 315 had fallen from 22·5 to about 17·5.

The current through the iron wire was then increased, by an alteration of the rheostat, to 2 amperes, and, as appears in the last column of the table, there was again a marked increase of the maximum elongation, and decrease of the retraction in a field of 315.

TABLE I.—*Iron Wire, diameter* 0·75 *mm.*

Magnetic field due to coil. C.G.S. units.	Elongations in ten-millionths of lengths.		
	With no current through wire.	With 1 ampere through wire.	With 2 amperes through wire.
13	3	7	
16	6	9	11·5

244	13·5		
250	—	−9	−5
315	−22·5		
319	—	18·5	
323	—		−13

For the sake of easy comparison, the principal results obtained with this wire are collected in Table II.

TABLE II.—*Iron Wire, diameter* 0·75 *mm.*

Current through iron wire. Amperes.	Maximum elongation in ten-millionths of length.	Retraction in field of 315 C.G.S. units.	Field in which length is unchanged.
0	11·5	22·5	130
1	14·5	17·5	170
2	20	12	200

Similar experiments were afterwards made with nickel and cobalt.

A nickel wire was used, the diameter of which was 0·65 mm. The retractions which it underwent in fields of gradually increasing strength are given in the second column of Table III.

TABLE III.—*Nickel Wire, diameter* 0·65 *mm.*

Magnetic field due to coil. C.G.S. units.	Retractions in ten-millionths of length.		
	With no current through wire.	With 1 ampere through wire.	Difference.
12	8	8	0
15	10	11	−1
19	15	15	0
28	25·5	25	0·5
36	34	33	1
50	50	48	2
69	74	72	2
84	92	92	0
99	113	112	1
119	134	133	1
150	164	162	2
175	178	178	0
209	196	194	2
256	217	215	2
330	241	240	1

The retractions of the wire when carrying a current of 1 ampere, are given in the third column of the table. Remembering that the figures in the second and third columns denote millionths of a centimetre, the close agreement between the two is very remarkable. Such small discrepancies as exist can hardly be entirely accounted for by observational or instrumental errors; they are probably mainly due to the effect of the rise of temperature (2°·6 C.) caused by the current in diminishing the susceptibility of the nickel.

Tension has a large effect upon the magnetic retraction of nickel: it is, therefore, the more remarkable that the action of a current, which operates so markedly upon iron, should in nickel be practically insensible.

The results with no current obtained for a strip of rolled cobalt, the length of which between the clamps was 10 cm., and the cross section 1·82 sq. mm., are given in the first two columns of Table IV., and those with a current of 2 amperes in the third column.

TABLE IV.—*Cobalt Strip, section* 1·82 *sq. mm.*

Magnetic field due to coil. C.G.S. units.	Retraction in ten-millionths of length.		
	With no current through strip.	With 2 amperes through strip.	Difference.
34	1	1	0
50	2	2·5	−0·5
84	4	5	−1
100	6	6	0
119	7·5	8·5	−1
153	11	11·5	−0·5
209	16	16·5	−0·5
331	26	27·5	−1·5

From an inspection of the differences tabulated in the fourth column, it appears that the effect of the current is to increase the retraction very slightly.

According to Rowland the susceptibility of cobalt is *increased* by heating. The small additional retraction indicated when the current was passing was, therefore, no doubt due to the increased susceptibility consequent upon current heating. It may be noted that tension seems to have no material effect upon the magnetic retraction of cobalt.

Summary.

In an iron wire carrying a current, the maximum magnetic elongation is greater, and the retraction in strong fields is less, than when no current is passing. The effect of the current is opposite to that of tension.

The magnetic retractions of nickel and of cobalt are not sensibly affected by the passage of a current through the metals. (Tension considerably modifies the magnetic retraction of nickel, but not that of cobalt.)

"The Human Sacrum." By A. M. Paterson, M.D., Professor of Anatomy in University College, Dundee, St. Andrews University. Communicated by Prof. D. J. Cunningham, D.Sc., F.R.S.

Chemical Society, May 19.—Prof. A. Crum Brown, F.R.S., President, in the chair.—The President announced that the Council had adopted a resolution expressive of the loss the Society and chemists generally had suffered by the death, on May 5, of Prof. von Hofmann. The resolution would be communicated to the family of the deceased, and to the German Chemical Society.—The following papers were read:—The magnetic rotation of compounds supposed to contain acetyl, or of ketonic origin, by W. H. Perkin. The author draws attention to Brühl's determination of the refractive powers of ethyl acetoacetate, which favours a ketonic constitution, and to its magnetic rotation, which was determined some years ago by himself, and which also supports this view. A list is then given of seven supposed acetyl compounds, of which he has ascertained the magnetic rotation, all giving numbers pointing to a ketonic constitution. As such compounds as these behave sometimes as ketonic and sometimes as hydroxy-derivatives, it was thought desirable to examine a larger number of compounds supposed to contain acetyl, or of ketonic origin, between wide limits of temperature. The following were selected: pyruvic acid, levulinic acid (fused and in solution), ethyl acetonedicarboxylate, ethyl acetoacetate, acetylacetone, methylacetylacetone, and ethyl β-amidocrotonate. The last-mentioned four were examined at widely different temperatures. The magnetic rotations of the first five substances agree with a ketonic constitution, though that obtained for ethyl acetonedicarboxylate is rather high. The rotation of acetylacetone is very high, showing it to be an unsaturated or hydroxy-compound, whilst the value obtained for methylacetylacetone stands between the hydroxy and ketonic rotations. At temperatures near 100°, however, these compounds give much lower rotations than when cold, showing apparently that they change into the more stable or ketonic form when heated. The refractive and dispersive powers of these compounds confirm the magnetic rotations. The magnetic rotation and the refractive and dispersive powers of ethyl β-amidocrotonate show it to be an unsaturated compound.—The origin of colour: ii. The constitution of coloured nitro-compounds, by H. E. Armstrong. The author has previously maintained that colour is conditioned by a quinonoid structure in the case of azo-dyes, such as the rosanilines, methylene-blue, &c. This view is clearly seen to be recommending itself to chemists. Nietzki makes reference to the quinonoid character of a number of dye-stuffs, although he does not seek to apply such a view at all generally. The author considers that, in the case of coloured compounds which have been fairly well studied, it is so generally true that a quinonoid formula is applicable, that the reconsideration of the formula of any coloured substance is warrantable if it do not come within the rule. The term "quinonoid" must, however, be understood to include compounds of the type of benzil, and in the case of closed chain compounds, it appears to be essential that at least one of the quinonoid carbon atoms be associated with a dyad radicle, and that the ring itself be unsaturated. The presence of two ortho- or para-carbonyl groups in a saturated ring apparently does not condition colour. Nitro-compounds as a class do not come within the suggested colour-rule. It is well-known, however, that nitro-compounds are not all coloured, many which are commonly described as yellow, being obtained white if prepared with care; from this it follows that the nitro-group does not *per se* condition colour. This is confirmed by a comparison of ortho- and para-nitrophenol. The ortho-compound is intensely yellow, very volatile, and insoluble in water; paranitrophenol is colourless, non-volatile with steam, and fairly soluble in water. Such a difference as this can hardly be ascribed to a mere change in the relative positions of the radicles. The difference is rendered all the more striking when the substances are contrasted with the methoxy-compounds prepared from ortho- and para-nitrophenol. These two substances are colourless, and agree as closely in their general properties as do most isomeric compounds containing the same radicles. It therefore appears justifiable to represent orthonitrophenol by a quinonoid formula—$C_6H_4 : O . NO_2H$, and to term it quinoneorthonitroxime. As only para- and ortho-compounds can have quinonoid formulæ, it would follow that metanitro-derivatives must be colourless; actually, however, metanitraniline has an intense yellow colour, but gives a colourless benzoate. The present view of its constitution therefore requires revision.—The origin of colour. iii. Colour as an evidence of isodynamic change: the existence of isodynamic acids, by H. E. Armstrong. The author applies the colour-rule dwelt on in the preceding paper to the cases of the coloured substances known as paradihydroxyterephthalic acid, dihydroxypyromellithic acid, and the corresponding "diamido" acids. These may be represented as quinonoid compounds, thereby accounting for their being coloured. Such substances as these readily change in type, yielding derivatives which may be colourless owing to conversion into an isodynamic form.—Studies on isomeric change, No. iv: Halogen derivatives of quinone, Part i., by A. R. Ling. Paradichloroquinone on bromination does not yield metadichlorodibromoquinone, as stated by Hantzsch and Schniter, but the normal product, paradichlorodibromoquinone. Contrary to the statement of Levy, this latter substance does not furnish chlorobromanilic acid on treatment with alkali, but a compound of one molecular proportion of chloranilate and two of bromanilate. Metadichloroquinone on bromination at a high temperature yields paradichlorodibromoquinone, but at ordinary temperatures the normal product, metadichlorodibromoquinone is chiefly obtained. A number of new compounds are described.—Halogen derivatives of quinone, Part ii., by A. R. Ling and J. L. Baker. Chlorotribromoquinone is prepared by brominating monochloroquinol and subsequently oxidizing the product. On treatment with alkali, it generally yields a molecular compound of the composition $C_6ClBr(ONa)_2O_2,2C_6Br_2(ONa)_2O_2$; $12H_2O$. Trichlorobromoquinone is obtained by brominating trichloroquinone. On treatment with soda, it yields the compound $C_6Cl_2(ONa)_2O_2$, $2C_6ClBr(ONa)_2O_2$; $10\frac{1}{2}H_2O$.—The crystalline forms of the sodium salts of substituted anilic acids, by W. J. Pope. A comparison of the crystallographic dimensions of the sodium salts of the brominated and chlorinated anilic acids referred to in the two preceding papers shows that the crystals possess considerable similarity.—Formation of a hydrocarbon, $C_{18}H_{12}$, from phenylpropionic acid, by F. S. Kipping. When phenylpropionic acid is treated with phosphoric anhydride, a resinous mass is obtained which contains at least three products. The first of these is a hydrocarbon, $C_{18}H_{12}$, which is oxidized by chromic acid mixture to a quinone, $C_{18}H_{10}O_2$. The hydrocarbon yields a dibromo-derivative, $C_{18}H_{10}Br_2$. The second product is a substance which yields a hydrazone of the composition $C_{15}H_{14}N_2$. It may possibly be  $C_6H_4 \left\langle \begin{matrix} CH_2 \\ CO \end{matrix} \right\rangle CH_2$, owing to the fact that it seems to be formed on treating phenylpropionic chloride with aluminium chloride. The third substance produced seems to be an organic derivative of phosphoric acid.—Metallic derivatives of acetylene, by R. T. Plimpton. The silver compounds of acetylene, obtained by several methods, viz. by precipitation of silver acetate or ammoniacal silver nitrate solutions with acetylene, on analysis gave numbers lying between those required for $C_2Ag_2,\frac{1}{2}H_2O$, and $C_2Ag_2.\frac{1}{3}H_2O$. Aqueous or alcoholic silver nitrate solutions yield precipitates varying in composition from $3C_2Ag_2,2AgNO_3,H_2O$, and $C_2Ag_2,2AgNO_3,H_2O$. Silver sulphate solutions gave a product of the composition $2C_2Ag_2,Ag_2SO_4,H_2O$. Mercuric acetate solution gives a white precipitate with acetylene, of the composition $3HgO,2C_2H_2$, which is not explosive, and does not yield acetylene when treated with hydrochloric acid. In these two properties this substance differs from the precipitate obtained from mercurous acetate.—Isomerism amongst the substituted thioureas, by A. E. Dixon. The author has prepared and examined the properties of isomerides of methylphenylbenzylthiourea and dimethylphenylthiourea.—Note on diastatic action, by E. R. Moritz and T. A. Glendinning. The authors draw the following conclusions from a series of experiments on diastatic action. The attainment of a resting stage in the transformation of starch by diastase by no means shows that the energy of the diastase is exhausted. The energy of the "residual" diastase is, in fact, very considerable, but it is lessened to a marked extent by subjecting the diastase for some time to a temperature exceeding the optimum one for saccharification. When, however, it is not exposed for any length of time to a temperature exceeding the optimum, it appears capable, after transforming a considerable amount of starch, of transforming further quantities to nearly the same point, when such further quantities are added successively and subsequent to the attainment of the resting stage in the preceding transformation.

Zoological Society, May 17.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. W. T. Blanford, F.R.S., exhibited and made remarks on the skin of a Wild Camel obtained by Major C. S. Cumberland in Eastern Turkestan.—In a paper on the geographical distribution of the Land-Mollusca of the Philippine Islands, the Rev. A. H. Cooke showed that the distribution of the different subgenera of *Cochlostyla* affords an interesting clue to the early relations of the various islands of the Philippine group. Regarded from this point of view, the central islands, Samar, Leyte, Bohol, Cebu, Negros, and Panay, with Luzon, were closely related, while Mindoro and Mindanao were remarkably isolated even from their nearest neighbours. An examination of the intervening seas accounted for these phenomena, the depths between the central islands being inconsiderable, while Mindoro and Mindanao are surrounded by very deep water. The Mollusca of the two ridges between the Philippines and Borneo, formed by Busuanga, Palawan, and Balabac, and by the Sulu Archipelago, were partly Philippine, partly Indo-Malay. Two remarkable groups of *Helix*, peculiar to Mindoro, Busuanga, and Palawan, showed relations with Celebes and possibly with New Guinea. The Mollusca of the Batan, Tular, and Talantse Islands were also discussed. Regarded as a whole, the Land-Mollusca of the Philippines were stated to contain: (1) Indo-Malay, (2) Polynesian, (3) indigenous elements, the first decidedly predominating.—A communication was read from Graf Hans von Berlepsch, and M. Jean Stolzmann, containing an account of a collection of birds made by M. Jean Kalinowski in the vicinity of Lima and Ica, in Western Peru. The species of which examples were obtained in the localities were eighty in number. In an appendix an account of previous authorities on the same subject was added.—Mr. G. A. Boulenger gave an account of *Lucioperca marina*, a rare species of fish, originally described by Pallas from the Black Sea and the Caspian, and little known of late years.—A communication from Mr. Oldfield Thomas contained a revision of the Antelopes of the genus *Cephalolophus*, of which eighteen species were recognized as valid. A new species was described as *Cephalolophus jentincki*, from Liberia.—Prof. Bell called attention to the remarkable amount of variation presented by *Pontaster tenuispinis*, numerous examples of which he had been able to examine and compare. He came to the conclusion that several North-Atlantic species, which had been described as distinct, should be regarded as belonging to it.—A communication was read from Mr. H. H. Druce giving an account of the Butterflies of the family Lycænidæ, of the South Pacific Islands. Of thirty-one species mentioned, seven were described as new to science.

Linnean Society, May 24.—Anniversary Meeting.—Prof. Stewart, President, in the chair.—The Treasurer presented his annual report duly audited, and the Secretary having announced the elections and deaths during the past twelve months, the usual ballot took place for new members of Council, when the following were elected: Messrs. E. L. Batters, William Carruthers, Herbert Druce, Spencer Moore, and Dr. D. H. Scott. The President and officers were re-elected. The Librarian's report having been read, and certain formal business having been transacted, the President delivered his annual address, taking for his subject "Commensalism and Symbiosis." On the motion of Dr. R. C. A. Prior, seconded by Mr. Jenner Weir, a cordial vote of thanks was accorded to the President for his able address, with a request that he would allow it to be printed.—The Society's Gold Medal was then formally presented to Dr. Alfred Russel Wallace in recognition of the service rendered by him to zoological science by numerous valuable publications. After Dr. Wallace had replied, the President announced the gift by Dr. R. C. A. Prior of an oxyhydrogen lantern for use at the evening meetings, and moved a vote of thanks to him for his valuable donation. This having been carried by acclamation, the proceedings terminated.

CAMBRIDGE.

Philosophical Society, May 2.—Prof. G. H. Darwin, President, in the chair.—The following communication was made:—Note on the application of the spherometer to surfaces not spherical, by Mr. J. Larmor. The ordinary form of spherometer, with equilateral triangular frame, gives a definite reading, when applied to a surface of double curvature, which corresponds to the arithmetic mean of the principal curvatures at the point; thus on a cylinder it will indicate half the curvature. It may be modified in various ways so as to measure both the principal curvatures by two observations.

May 16.—Prof. G. H. Darwin, President, in the chair.—The following communications were made:—Recent advances in astronomy with photographic illustrations, by Mr. H. F. Newall. A series of photographs was exhibited by the lantern and described, to illustrate recent progress in astronomical photography. The series included some interesting specimens taken with the Newall telescope, in which the object-glass is not specially corrected for photographic purposes.—On the pressure at which the electric strength of a gas is a minimum, by Prof. J. J. Thomson. The author showed that when no electrodes are present, the discharge passes through air at a pressure somewhat less than that due to 1/250 mm. of mercury; the discharge passes with greater ease than it does at either a higher or a lower pressure. Mr. Peace has lately shown that when electrodes are used, the critical pressure may be as high as that due to 250 mm. of mercury; so that as the spark length is altered the critical pressure may range from 250 mm. to 1/250 of a mm. It was pointed out that this involved the possession by a gas conveying the discharge of a structure much coarser than any recognized by the kinetic theory of gases. The author suggested a theory of such a structure, and showed that the theory would account for the influence of spark length and pressure on the potential difference required to produce discharge.—On a compound magnetometer for testing the magnetic properties of iron and steel, by Mr. G. F. C. Searle. An aluminium wire, 30 inches long, suspended vertically by a fibre, carries at the top a magnet fixed at right angles to the wire. The lower end carries a light fork across which a fibre is stretched horizontally. A mirror attached to this fibre carries a magnet at right angles to the fibre. The mirror is thus capable of two independent motions. The specimen of iron is placed in a magnetizing coil near the mirror, and the magnetizing current passes also round a coil placed near the upper magnet. The motion of the mirror is observed by the aid of a spot of light. On gradually increasing and diminishing the current, the spot traces out the well-known hysteresis curves.

EDINBURGH.

Royal Society, May 16.—Sir Douglas Maclagan, President, in the chair.—The Astronomer-Royal for Scotland exhibited a stellar photograph, by Dr. Gill, of the Cape Observatory.—Dr. W. Peddie read a note on the law of transformation of energy and its applications. A generalization of the second law, applicable to forms of energy other than heat, was shown, by special examples, to lead to results already deduced by other methods.—Dr. C. G. Knott and Mr. A. Shand communicated a short note on the volume-effects of magnetization, which was supplementary to results communicated to the Society last year by the former author. When a particular size of iron tube was magnetized, the internal volume was found to undergo the following remarkable series of changes. In very weak fields there was first a slight increase, which, as the field was made stronger, passed through a maximum, then vanished and finally changed sign. From this point (about field 20) up to a field of 120 there was diminution of volume. This diminution was greatest in a field of 64. In fields higher than 120 there was again increase of volume, which attained a maximum about field 400, and fell off very slowly in higher fields. This curious variation of cubical dilatation with strength of field was shown to imply a transverse linear dilatation of (in general) opposite sign to the well-known longitudinal linear dilatation. The amounts, the positions of the maximum points, and of the vanishing points, of these correlated linear dilatations differed sufficiently in detail to produce this peculiar repeated change of sign in the cubical dilatation.—Dr. Hunter Stewart read a paper on the ventilation of schools and public buildings. The first part of the paper contained an account of an investigation as to the presence of organic nitrogenous matter in expired air. Several methods were used for absorbing and collecting these products, *e.g.* breathing through strong sulphuric acid, condensing the moisture from the breath, &c. The organic matter was determined by the process of Kjeldahl, by which the nitrogen is converted into ammonia. The results showed that each cubic foot of expired air contained on an average 0·01149 milligrams of ammonia as such, and 0·002 milligrams of ammonia derived from organic matter. The water condensed from 10 cubic feet of expired air contained on an average 0·5 milligrams of solid residue which entirely disappeared on ignition. These results, confirmatory of the observations of Hermann and Lehmann, proved that the organic matter in badly ventilated rooms did not come from the breath, but from the skin and clothing of the occupants. Since this must be variable, depending on obvious conditions, Dr. Stewart did not determine it, but relied on the estimation of the carbonic acid and moisture as a measure of the efficiency of the ventilation. The following are some of his results taken as averages:—

Edinburgh Hospitals, with 2000 cubic feet of space per bed—				
	Day	5·5 c.c. CO_2 per 10,000		
	Night	5·85	,,	,,
Churches	Highest	63·5	,,	,,
	Lowest	20·0	,,	,,
Schools, with, per child,				
	154 c. ft. space and 9·8 sq. ft. area	9·9	,,	,,
	141 ,, ,, 8·8 ,,	13·3	,,	,,
	116 ,, ,, 7·1 ,,	17·2	,,	,,

All the schools and churches were without mechanical ventilation.—Prof. James Geikie read a paper on the glacial succession in Europe. The deposits which first give evidence of glacial action are generally referred to the Pliocene period. These are the oldest ground moraines of Central Europe, the ground moraine underlying the "lower diluvium" of Sweden, and the deposits of the Weybourne Crag with their Arctic marine fauna. Genial climatic conditions followed this period, with a wide land area, Britain being joined to the continent. Then followed the epoch of maximum glaciation, the Scottish and Scandinavian ice-sheets being continuous. Genial climatic conditions followed, Britain being again continental. Then submergence ensued to the 500-feet level, followed by another glacial epoch in which the Scottish and Scandinavian ice-sheets were again continuous. This was succeeded by genial conditions, Britain being once more joined to the continent. Submergence to the 100-feet level in Scotland followed, and then came Arctic conditions with local ice-sheets, succeeded by temperate conditions and the wide land area, and subsequently by submergence to the 50-feet level. Another cold period followed with local glaciers—the last in Britain.

Paris.

Academy of Sciences, May 30.—M. d'Abbadie in the chair.—Introduction of M. Guyon, the new member elected in the place of M. Richet.—Observations of the small planets, made with the great meridian instrument of the Paris Observatory during the second and third quarters of the year 1891, by M. Mouchez.—On the propagation of electrical oscillations, by M. H. Poincaré. The disturbance is supposed to be propagated along a thin straight conductor. The enfeeblement of the disturbance is theoretically shown to vanish when the diameter of the conductor becomes indefinitely small.—Another blow to the ascent theory of cyclones, by M. Faye. A discussion of recent observations, showing that cyclones are not produced by convection from the soil, but by disturbances in the general circulation of air in the higher regions.—On the monkey of Montsaunès discovered by M. Harlé, by M. Albert Gaudry. A portion of the mandible of a monkey, containing three teeth, was exhibited, found by M. Harlé, engineer at Toulouse, in the Quaternary of the Haute-Garonne. It shows the greatest similarity with the magot of Gibraltar and Algiers.—Physiological effects of a liquid extracted from the sexual glands, and especially the testicles, by M. Brown-Séquard.—On the relations of the Devonian and Carboniferous formations of Visé, by M. J. Gosselet.—Study of the physical and chemical phenomena under the influence of very low temperatures, by M. Raoul Pictet. The calorific æther waves corresponding to low temperatures are found to traverse all bodies with hardly any resistance. A test-tube filled with chloroform was placed in a nitrous oxide refrigerator at -120°. A thermometer in the tube showed a gradual fall to $-68^\circ\cdot5$, when crystallization commenced. On removing the test-tube to a refrigerator at -80°, the temperature indicated by the thermometer *fell rapidly* from $-68^\circ\cdot5$ to -80°, while the crystals formed on the walls of the test-tube fused and disappeared. On replacing it into the -120° refrigerator, the temperature rose to $-68^\circ\cdot5$, and the crystals reappeared. M. Pictet explains these extraordinary phenomena by supposing his thermometers to have acted more as thermodynamometers than as thermoscopes. While the crystals were forming in the first refrigerator, the radiation from the bulb was neutralized by the latent heat given out by the chloroform in crystallizing, whereas in the warmer refrigerator the crystals did not form, and radiation alone was active. Alcohol and sulphuric ether thermometers were used, which were checked by thermometers containing dry hydrogen at four different pressures.—On rectangular co-ordinates, by M. Hatt.—On the application of the optical properties of minerals to the study of the inclosures in volcanic rocks, by M. A. Lacroix.—On a property common to three groups of two polygons, inscribed, circumscribed, or conjugate to the same conic, by M. Paul Serret.—On the canonical developments in series the coefficients of which are differential invariants of a continuous group, by M. Arthur Tresse.—On the calculation of the coefficient of resistance of air, supposing the resistance proportional to the fourth power of the velocity, by M. de Sparre.—On a means of bringing two non-miscible liquids into intimate contact in definite proportions, by M. Paul Marix. This is done by pouring both liquids into the same vessel at a definite rate, and allowing them to leave it by an orifice in the side. They will escape together in the proportion of their volumes, if the level of the liquid is maintained uniform by a constant supply. The surface of separation is invariably found at the level of the orifice, and if a flattened spout is used, a lamellar arrangement of the liquids is produced, thus giving a large surface of contact.—On a hydro-silicate of cadmium, by MM. G. Rousseau and G. Tite. This is produced by the action of the glass vessel when the solid hydrate of neutral cadmium nitrate is heated to about 300°. On dissolving away the basic nitrate with boiling alcohol, the silicate can be detached from the glass in long scales by hot water. Its formula is $2(CdO, SiO_2) . 3H_2O$.—On the decomposition by heat of ammoniacal pentachloride of phosphorus, nitrochloride of phosphorus, and phosphame, by M. A. Besson.—On the phosphates of strontium, by M. L. Barthe.—The calorific power of pit-coal and the formulæ by means of which its determination is attempted, by M. Scheurer-Kestner.—Mechanical determination of the boiling-points of terminal complex substitution products, by M. G. Hinrichs.—On some reactions of the three amido-benzoic acids, by M. Œchsner de Coninck.—On the composition of chlorocruorine, by M. A. B. Griffiths.—On the antiseptic properties of formaldehyde, by M. A. Trillat.—The nervous system of the Neritidæ, by M. E. L. Bouvier.—On the osteological characters of a male *Mesoplodon Sowerbyensis* recently stranded on the French coast, by M. P. Fischer.—On a new species of *Gammarus* of the Lac d'Annecy, and on the fresh-water Amphipoda of France, by MM. E. Chevreux and J. de Guerne.—Action of various toxic substances on *Bombyx Mori*, by M. J. Raulin.—On the genetic relations of resinous and tannic substances of vegetable origin, by MM. Edouard Heckel and Fr. Schlagdenhauffen.—Researches on the grafting of Crucifers, by M. Lucien Daniel.—Contribution to the study of the toxic effect of the diphtheria bacillus, by M. Guinochet.—Contribution to the knowledge of the Saharian climate, by M. Georges Rolland. A summary of observations made at a meteorological station in the oasis of Ayata, in Southern Algiers. The sparse vegetation found here and there seems to derive its moisture from subterranean sources, whence it ascends by capillary attraction, and from certain deliquescent salts found in the soil which absorb moisture at night.—On a passage in Strabo relating to a treatment of the vine, by M. Ant. Aublez.

MECHANICS.

A Treatise on Analytical Statics. With numerous Examples. Vol. I. By Edward John Routh, Sc.D., LL.D., F.R.S., Hon. Fellow of Peterhouse, Cambridge; Fellow of the Senate of the University of London. (London: Macmillan and Co., 1891.)

The Elementary Part of a Treatise on the Dynamics of a System of Rigid Bodies. Being Part I. of a Treatise on the Whole Subject. With numerous Examples. By the Same. (London: Macmillan and Co., 1891.)

WITH these two volumes the mathematical student is completely equipped for the course of Analytical Mechanics, as required for Part I. of the Cambridge Mathematical Tripos.

A second volume is promised of the "Analytical Statics," to cover the parts in Attraction, Astatics, and the Bending of Beams; and this, in conjunction with Part II. of the "Dynamics," will complete his library for the second part of the Mathematical Tripos, according to present regulations.

The great feature of these works is the very complete collections of examples which the author has brought together with great labour, and enriched with many of his own invention, fit to rank among the theorems of the science, rather than as mere problems.

The author is of the opinion that in order to learn Mechanics it is essential to the student to work many examples, taken as far as possible from questions that have actually arisen.

In this opinion he agrees with Fourier, who says:—

> "L'étude approfondie de la nature est la source la plus féconde des découvertes mathématiques. Non seulement cette étude, en offrant aux recherches un but déterminé, a l'avantage d'exclure les questions vagues et les calculs sans issue; elle est encore un moyen assuré de former l'Analyse elle-même," &c.

This is an opinion, however, that has always divided mathematicians into rival camps, and we find Jacobi remonstrating with these words of Fourier by retaliating:—

> "Il est vrai que M. Fourier avait l'opinion que le but principal des mathématiques était l'utilité publique et l'explication des phénomènes naturels; mais un philosophe comme lui aurait dû savoir que le but unique de la science c'est l'honneur de l'esprit humain; et que sous ce titre, une question de nombres vaut autant qu'une question du système du monde."

The developments of mathematics are now so great that specialization is a necessity, so that these rival theories need not come into collision; and the pure mathematician may allow the writer on Mechanics to treat of what the name of the subject implies without being compelled to regard his own Geometry as mere Land-Surveying, according to the strict meaning of the word.

There is a tendency in operation among certain mathematicians, as illustrated by Poincaré's remarks on Maxwell's writings, to degrade mathematical argument to mere Calcul, by reducing the experimental facts on which the theory is based to the barest minimum, and that not always clearly established (we venture to instance the Newtonian Law of Universal Gravitation). A vast array of Analysis is in consequence balanced upon a very small amount of axiomatic experiment, which in many cases the smallest divergence of experimental fact is sufficient to upset.

We had hoped at the outset that Duchayla's proof of the Parallelogram of Forces had disappeared, never to reappear again, but it unfortunately pops up on p. 16.

Considering that Statics deals with the Equilibrium of Bodies would make a great simplification if the word Resultant was abolished, unless when required to mean a single force reversed of a system of equilibrating forces.

In this way a much simpler proof of the Parallelogram of Forces can be constructed, as indicated by Prof. Maxwell in the Mathematical Tripos; and one figure will now serve for all the possible cases arising in the equilibrium of three parallel forces (p. 47).

Again, when the system is in equilibrium, there is no need to introduce the restriction that the bodies are *rigid* (p. 12); the conditions are precisely the same for elastic bodies; but the system having come to rest, the parts are of invariable form. Every structure (the Forth Bridge, for instance) is composed of elastic parts, but the theorems of elementary Statics are still applicable in the investigation of the principal stresses.

Again, by considering balancing couples, the refined theorems concerning the equivalence of couples in the same or parallel planes, and the composition of couples in different planes, are rendered much more convincing.

In accordance with its title of "Analytical Statics," the theorems concerning the composition and equilibrium of forces in space are treated with reference to co-ordinate axes; but Sir Robert Ball's purely geometrical conceptions of the Wrench, Screw, and Cylindroid are introduced, and discussed from a fundamental standpoint.

A chapter on the determination of Centre of Gravity appears in all treatises on Analytical Statics, just as works on Rigid Dynamics begin with a long and tedious chapter on Moments of Inertia: these subjects should form part of the ordinary treatises on Integral Calculus, and so relieve treatises on Mechanics from at least the principal elements of such calculations.

In the application of the Barycentric Calculus to geometry, the author has made a very interesting collection of problems, well calculated to illustrate the power of this method.

The principal theorems of Statics involve profound geometrical argument, and consequently prove difficult to the majority of students, whose proclivities are usually analytical; but in the applications to Catenaries the analytical interest comes again to the front. Considering that the hyperbolic functions can now be obtained tabulated numerically—for instance, in a table by Mr. T. H. Blakesley, published by the Physical Society—it is curious that the author does not employ them in the discussion of the ordinary Catenary, where their use introduces great elegance and simplicity into the analysis. The figure of the Catenary on p. 316 might with advantage be redrawn, so as to exhibit accurately the principal properties of this curve.

Again, in Example 6, p. 352, where the problem of the catenary is discussed under a central attraction or repulsion, varying inversely as the square of the distance, when the hyperbolic functions are used in conjunction with the circular functions, we are able to write the equation of the catenary in the form—

$$l/r = 1 + \sec\alpha\cos(\theta\sin\alpha),\quad\text{or } 1 + \operatorname{sech}\alpha\cosh(\theta\sinh\alpha),$$

including all possible cases; and it is a curious geometrical result that if these curves are rolled on a straight line, the pole will always describe a circle.

The treatment in § 500 of the catenary curve formed by an elastic rope can also be rendered more elegant by the introduction of the hyperbolic functions.

The chapter relating to Catenaries is headed "Strings." But *string* is used only for tying up parcels; we use a *rope* or *chain* in full scale mechanics, and *thread* in a model; the word *thread* should be used when its own weight is to be neglected, and the words *rope* or *chain* when applied to a true catenary.

A short chapter on Graphical Statics is very welcome, and might with advantage be further developed; and the final chapter, on Machines, is of the usual academic character. The interest of this chapter would be much increased if the diagrams, particularly of the Balance and of the Differential Pulley were taken from objects actually in existence.

The author never employs the absolute units of force, the *poundal* or *dyne*, which he has defined in Chapter I., but works throughout with the gravitation unit. This is in accordance with the universal practice; and to satisfy legal and commercial requirements, these absolute units would require to be defined through the intermediate of the gravitation unit, by taking them as one-gth part of the tension of a thread supporting a pound or gramme weight, the value of g being determined from pendulum experiments. There is no apparatus in existence by which the theoretical definition of the poundal and dyne, derived from dynamical phenomena, could be tested with any pretence to accuracy.

The dyne is the unit of force in the C.G.S. system, but it is a great pity that the commercial units, the metre and the kilogramme, were not adopted; the unit of energy would then be the *joule*, and the unit of power the *watt* or *volt-ampere*. Merely, apparently, for the purpose of making

$$W = sV, \text{ instead of } 1000sV,$$

the Committee of the British Association recommended these niggling C.G.S. units; but considering that for ordinary substances, metals, &c., variations of texture render it unnecessary to tabulate densities beyond four significant figures, the factor 1000 is a positive advantage in numerical calculations, as $1000s$ may be replaced by a whole number.

The "Analytical Statics" is a completely new work, but Dr. Routh's "Dynamics of Rigid Bodies" has been the text-book in universal use for thirty years or more, a better testimony to its merits than anything that could be said here.

It is a pity that a sufficient working knowledge of the simple ideas of Moment of Inertia is not given in a course of the Integral Calculus, so that the author might start immediately on some familiar problems of the motion of a body which turns as well as advances, and relegate the bulk of Chapter I. to a later chapter, when the motion of bodies in space is considered. This long chapter at the outset chokes off many students, who would be encouraged if the principles were introduced in smaller doses, and only as required. The gentlemanly knowledge of this subject, as Maxwell called it, which does not go beyond motion in a plane, is a very valuable mathematical training, and few students go beyond this stage.

D'Alembert's Principle is historically important, as a first clear statement of the mode of forming the equations of motion; but now, in accordance with the modern principle of considering the Third Law of Motion, "Action and Reaction are equal and opposite," as defining a stress composed of two equal opposite balancing forces, D'Alembert's Principle should now be merely looked upon as a convenient mode of writing down the equations of Dynamics in an analytical statical form, when stated in the words, "The reversed effective forces and the impressed forces form a system in equilibrium," while "the molecular, cohesive, or internal forces form a system in equilibrium among themselves."

The much-abused word "centrifugal force" still survives, and need not cause confusion if used to denote the normal component of the reversed effective force of a body moving in a curve.

Early methods of argument in Dynamics were very similar to what we now employ in Thermodynamics, in the statement of the Second Law.

Sir George Airy's commentary on D'Alembert's Principle, quoted on p. 52, forms a very curious contrast to the corresponding explanation in Maxwell's "Matter and Motion."

It would be a strange skeleton frame that Sir George Airy would have had to create to propagate the attraction between the Earth and the Moon or Sun; and an interesting subject of speculation arises as to the modification of Newton's Law of Universal Gravitation when the inertia of the skeleton frame became appreciable.

The discussion on the Pendulum is very complete; Kater's pendulum is fully described, but we miss the account of Repsold's pendulum. In this pendulum the effect of the drag of the air is eliminated by making it symmetrical in shape, but unsymmetrical in density. A short account of Repsold's pendulum will be found in the Account of the Great Trigonometrical Survey; but the pendulum is obviously looked upon with suspicion by our officers, as being employed by their Russian rivals on the other side of the Himalayas.

The very perfection of the pendulum as a method of determining g is the cause of its defect as a means of recovering the standard of length, so that equally skilled observers would differ to an appreciable extent if set to work to reconstitute the standard yard from the seconds pendulum; the clause in the Act of Parliament defining the length of the seconds pendulum is in consequence superfluous.

There is something mysterious and unconvincing in § 109, on the "Oscillation of the Watch Balance"; considering that the inertia of the spring itself is neglected, it seems that the final equation of oscillation might well be written down immediately, without the introduction of any approximation.

The Ballistic Pendulum and its theory are fully described; but it should be pointed out that the pendulum in which the gun itself is mounted gives very untrustworthy records, as the effect of the blast of the powder and of the air dragged along with it is so very great. The Ballistic Pendulum is still useful for determining the velocity of small-arm bullets, but for artillery purposes the electric chronograph has completely supplanted it.

Chapter IV. discusses Motion in Two Dimensions, and is perhaps the most generally important and interesting chapter in the book. A complete dynamical terminology is still a desideratum, and many new words must be coined; for, as De Morgan remarks, "We cannot wait for words, because Cicero did not know the Differential Calculus (or Dynamics)." At the same time it is a pity that the old word *Vis Viva*, meaning Mv^2, was not allowed to drop, to be replaced by *Kinetic Energy*, for $\frac{1}{2}Mv^2$. *Vis mortua* is forgotten as the name for *Work*, and *vis viva*, as the other manifestation of energy, should go too.

The dot notation of Fluxions has been introduced in places: this, though easy to write, is difficult to print, and is inconvenient sometimes with tall letters, while others, like i and j, are already in their "dotage."

Dr. Routh would, in our opinion, make the working of the illustrative examples more clear, if he always followed the fundamental principle of taking moments about the centre of gravity, as if it was a fixed point: very few students can be trusted to apply the principle to moments about any other moving point, and the equations of relative motion on p. 178 are better kept out of sight of all but a select few.

Dr. Besant's treatment of questions on Initial Motion is in our opinion simpler of application and quite as rigorous as that given in § 199.

A very good collection of illustrative examples completes this chapter, but we miss the extension of the problem of the motion of a cylinder rolling down an incline to the case of a wheeled carriage or of a railway train, when the rotary inertia of the wheels is taken into account, including the determination of the proper position of the coupling chains and buffers; also the investigation of the stresses in the interior of a swinging body like a ship, not only in causing cargo to shift, but also in its physiological bearing on sea-sickness. An ordinary swing is useless as an antidote to sea-sickness, as the seat is close to the centre of oscillation. To feel the disturbing effect we must mount up above the axis of revolution; and to the deck and up the mast of a ship.

As interesting applications, we may mention the dynamics of billiards, §§ 179–98, and of the quintain in § 178.

After Chapter IV. the author launches off into dynamics in space, and now the difficulty of the subject is more than doubled.

Chapter VII., on Energy (or Vis Viva, as Dr. Routh still prefers to call it), precedes in importance and idea the Chapter VI., on Momentum, and might well change place. The idea of energy as $\frac{1}{2}Wv^2/g$ very soon received a name for its unit in the *foot-pound*, but the corresponding name for the momentum, Wv/g, of *second-pound* is as yet hardly known.

In this chapter the Principles of Dynamical Similitude are discussed. In Geometry the Principle of Similitude asserts that a theorem is true whatever the scale on which it is drawn; but in Dynamics the principle is much more complicated, and great care is required in arguing from the performance of a model or of a machine to one to be constructed to a larger scale. The subject is one of great importance at the present time in the discussion of the design of steamers intended to reduce the time of passage across the Atlantic to something under six days; and the statement of the laws to be applied as affecting steamers, first clearly laid down by Mr. Froude, might well find explanation and illustration at this point.

The impact of two rough elastic ellipsoids is treated in §§ 315, &c., by a mathematical *tour de force;* but the expression *perfectly rough* is never met with outside a Cambridge mathematical treatise. What would be the state of things, for instance, between two bodies in contact, one *perfectly rough* and the other *perfectly smooth?* When we wish to produce this so-called perfect roughness between two bodies, we cut teeth on them, to engage together; and in railway travelling the perfect smoothness of the road due to the employment of wheels must be capable of being turned into roughness by the application of the breaks: the continuous breaks now fitted to express trains have enabled a higher average speed to be maintained.

The General Equations of Motion of Lagrange and Hamilton, discussed in Chapter VIII., are not to be employed by any but very advanced students: the formation of these equations and the conversion of one form into the other constituting difficult and refined applications of the Change of the Variables.

In the case where some of the co-ordinates are absent, this part of the subject has received valuable development from Dr. Routh, by means of a principle now called the Ignoration of Co-ordinates.

The volume concludes with an investigation of the Small Oscillations of a System, important as a Stability Test; in such problems the author expresses the result very concisely by means of the length of the simple equivalent pendulum which synchronizes with the oscillations. An interesting problem to discuss is the theory of Mr. Yarrow's Vibrometer, employed for measuring the vertical vibrations of his torpedo-boats: a platform suspended by springs is found to preserve a constant level, if the free period of the vertical oscillations of the platform is incommensurable with the period of the vibrations of the boat.

It is difficult to know where to stop in writing of treatises such as these two of Dr. Routh, so full of detail and interest; and the two treatises together would provide nearly a year's work for an industrious student, who would thereby derive a thoroughly sound and complete knowledge of the subjects.

A. G. Greenhill.

COLLECTIONS FROM THE ANDES.

Supplementary Appendix to Travels amongst the Great Andes of the Equator. By Edward Whymper. (London: John Murray, 1891.)

THOUGH many travellers in new or little-known regions, who are not naturalists, have been in the habit of collecting to some extent the more remarkable specimens which they have noticed, in various branches of the animal kingdom, yet, as a rule, both such collections and the reports upon them are more or less unsatisfactory to professed naturalists; partly because they usually represent mere fragments of the fauna of the regions explored, and partly because inexperienced collectors often pass over the most interesting species, and bring back common and wide-ranging forms of comparatively little interest.

Alpine climbers in particular, as a class, have done so little for zoology in Europe or the Caucasus, that we hardly expected that Mr. Whymper, whose reputation for daring, determination, and endurance, puts him among the most distinguished of Alpine climbers, would now turn his attention to zoology. He has, however, shown the best possible example to his *confrères* by his Great Andean expedition; and has proved that it is possible without in any way neglecting the special objects of his journey, to do most valuable zoological work; and as the higher regions of the Andes have been neglected by professional collectors, who depend more or less on their success for payment of expenses, the proportion of new Coleoptera brought home by him is very great. Owing, no doubt, to the late Mr. Bates's good advice, Mr. Whymper has secured the assistance of many specialists of eminence in describing his collections, and the work is profusely illustrated with wood-cuts of the highest class, better by far than many of the coloured illustrations which often appear in scientific periodicals.

The total number of species collected amounts, according to Mr. Bates, to about one thousand, but the Diptera, Lepidoptera-Heterocera, Hymenoptera (except the ants), and Arachnida have not been described, on account of the difficulty of finding anyone to work them up; and as the birds do not seem to have attracted much of Mr. Whymper's attention, and fishes are almost wanting in the higher mountain streams, the greater part of the book is taken up by descriptions of the Coleoptera by Messrs. Bates, Sharp, Gorham, Olliff, and others. Messrs. Godman and Salvin have written a chapter on the butterflies, but of these very few occur at elevations of 10,000 feet and upwards; and only two Satyridæ, two species of Lycæna, two Pieris, and two Colias, were taken at or above 12,000 feet. This is a strong proof of the poverty of the high Andes in endemic forms, as compared with the high Alps of Europe and Asia, where, notwithstanding the severity of the climate, a large number of species are found at elevations which, when allowance has been made for the latitude, are much higher than these. This may be accounted for to some extent by the weather, which appears to be, in the high Andes of Ecuador, very wet and windy during the whole year. It is farther explained by the late Mr. Bates in the following remarks, taken from the introduction which he has contributed to the volume:—

"It seems to me a fair deduction from the facts here set forth that no distinct traces of a migration during the lifetime of existing species, from north to south or *vice versâ*, along the Andes have as yet been discovered, or are now likely to be discovered. It does not follow, however, that the Darwinian explanation of the peculiar distribution of species and genera on mountains in the tropical and temperate zones, and in high latitudes of the Old World, is an erroneous one. The different state of things in the New World is probably due to the existence of some obstacle to free migration, as far as regards insects, between north and south, both during and since the Glacial epoch. The problem, like most others relating to geographical distribution, is a complicated one; but there are one or two considerations, likely to be overlooked, which may tend to its solution. One is the great altitude at which the vigorous denizens of the teeming tropical lowlands flourish on the slopes of the Andes. Mr. Whymper found, for example, species of many of the genera of Longicorn Coleoptera characteristic of the lowland forests at altitudes of 9000 and 10,000 feet, and Kirsch has recorded numerous species of *Lampyridæ*, *Lycidæ*, and other families belonging equally to tropical American forest genera, as met with by Reiss and Stübel in Colombia and Ecuador at 12,000 feet. In Ecuador all the warm moisture brought by the eastern trade-winds is not intercepted even now by the wall of the Andes, and wherever that falls, in the depressions, conditions of climate and vegetation will be created suitable to these encroaching tropical forms. If we add to this the barrenness and generally unfavourable conditions of the zone above those altitudes, there can be little wonder that temperate forms have not freely passed along the Andes. Another consideration is that there may have been a breach of continuity of the land in Glacial times, at the Isthmus of Panama, sufficient to prevent free migration. It may, further, be legitimate to speculate on the possibility of the Andes being lower in the tropical zone during the Glacial epoch. A few hundred feet lower than the present altitude, combined with the copious warm rains which must have accompanied the age of ice, would present conditions undoubtedly favourable to the spread of tropical forms over the whole area which would successfully resist the invasion of high northern or southern species. The main principle in distribution, however, is that forms sooner or later, and in proportion to their intrinsic and extrinsic facilities of dissemination, will find their way all over the world to wherever the conditions inorganic and organic are favourable to their acquiring a footing. That these facilities are possessed in a higher degree by plants than insects and some other groups of animals may be a sufficient explanation of the fact that so many species of plants have surmounted the obstacles to their passage from north to south during the last Glacial epoch, while few or no insects have done so. The more distant, or generic, relationship between the insects of Chili and those of the north temperate zone can only be explained on the assumption of a migration at some epoch far more remote than the last Glacial epoch."

Mr. Whymper's book as a whole is a remarkable example of his talent as an explorer, a mountain climber, and an accurate observer both of physical, geographical, and natural history phenomena, and though we have waited eleven years for its appearance, nothing has been lost and much has been gained by this delay, and his book will take rank among the very best works of scientific travel which have ever been written.

H. J. ELWES.

THE HISTORY OF EPIDEMICS.

A History of Epidemics in Great Britain from A.D. 664 *to the Extinction of Plague.* By Charles Creighton, M.A., M.D. (Cambridge: University Press, 1891.)

THE task undertaken by Dr. Charles Creighton in writing a history of epidemics in Britain from 664 (the year of the first pestilence recorded by an authority that can be regarded as contemporary) to the extinction of plague is one of enormous difficulty. The materials for such a history must be sought for high and low; chance allusions in private letters or municipal records will supply links in the chain of evidence for which the writings of the medical authorities of the time may be searched in vain, if indeed there be any medical authorities; and Dr. Creighton found that for his purposes "medical books proper are hardly available . . . until the end of the Elizabethan period, . . . and do not begin to be really important . . . until shortly before the date at which" his present labours end. When such evidence as can be found has been found and sifted, there still remains the most intricate problem of all—that of tracing the epidemics recorded to their origin, accounting for their spread, and in some cases explaining why a country should in modern times be spared diseases which scourged it in the Middle Ages.

No better illustration of these difficulties could be found than is supplied by chapter ii., "Leprosy in Mediæval Britain." The first point that Dr. Creighton has to make clear is that all the so-called lepers were not really lepers. In extreme cases the word "leprosus" may have been used simply as meaning "beggar or common tramp"; elsewhere it may have been applied to victims of syphilis, lupus, and so forth. For the sufferers special provision was no doubt made, on a scale due in part to a morbid or mistaken religious sentiment; but examination of the charters and other documents relating to these charities suggests that, of the supposed foundations for lepers, some were merely refuges for sick and infirm poor, in others provision was made for three or four times as many non-leprous as leprous inmates, while from others, towards the end of the thirteenth century, the lepers were disappearing or getting displaced. Finally, the author concludes that the prevalence of true leprosy at any time in England was probably not so great as in the worst provinces of India at the present day; but, however justifiable scepticism as to its supposed ravages may be, that the disease really did prevail can hardly be doubted, and the reasons for doubt are lessened, if a *vera causa* for its presence can be found. Such a *vera causa*, compatible with its subsequent disappearance, may be discovered, not in "importation," *e.g.* by Crusaders—a suggestion Dr. Creighton does not consider worth thinking about—but in the staple diet of the times, a semi-putrid or toxic character of animal food combining with other depressing influences to give rise to leprosy, just as a similar character of bread or porridge gives rise to pellagra.

We have given the arguments of this chapter somewhat in detail, because the criticism which obviously applies to them, applies elsewhere. Considering the uncertainty which surrounds the facts, it is clear that the traditions of the leprosy of the past cannot very materially assist, though they may be explained by, the study of modern leprosy. Similarly, in the case of the plague, to which naturally Dr. Creighton devotes much of his book, to say nothing of that old question, the value of the evidence of the Bills of Mortality, the inquirer is met at once by the great difficulty of knowing when "the plague" which is spoken of as invading out-of-the-way places really was the genuine plague—a point of vital importance, as soon as any etiological questions are raised, and we may here observe that Dr. Creighton writes :—

> "In concluding the career of the sweat in England, we may pass from it with the remark that it did not cease until other forms of pestilential fever were ready to take its place. The same explanation remains to be given of the total disappearance of the plague from England after 1666: it was superseded by pestilential contagious fever, a disease which was its congener, and had been establishing itself more and more steadily from year to year as the conditions of living in the towns were passing more and more from the mediæval type to the modern."

It would be impossible here to enter into the merits or the reverse of all Dr. Creighton's explanations of the facts he records. In the chapter on small-pox, which is likely to be the one first consulted, we find a passage which disarms criticism: "It has been the fate of small-pox as an epidemiological subject to be invested with bigotry and intolerance." Yellow fever has as yet hardly sunk to that deplorable level; and as Dr. Creighton's theory appears to be that "the dysenteric matters of the negroes" carried on the slave ships "had themselves in turn bred an infection of yellow fever for the whites," it may be asked whether the alleged protection of Africans of pure blood from the infection of yellow fever "in all circumstances ashore or afloat, . . . not by acclimatization but by some strange privilege of their race," is either supported by all recent authorities, or not capable of the explanation that in infancy they may pass through some disease too slight to be recognized as yellow fever, but which serves to confer immunity.

The general impression left upon the mind by this history is that it would have been a wise policy to make two books instead of one out of the materials collected —in one simply to bring together such facts as Dr. Creighton's industry has gleaned from the authorities, and in the other to enter upon the questions of etiology, which are bound to give rise to interminable discussion.

Besides those we have mentioned, gaol fevers, influenzas, "the French pox," and scurvy in early voyages, are the principal diseases treated of in this volume. In dealing with influenza Dr. Creighton draws attention to the relation in point of time between the outbreaks in the latter half of the sixteenth century and great epidemics of plague, and a somewhat similar relation between fever and influenza and exceptional climatic conditions in the years 1657-59.

OUR BOOK SHELF.

Mineralogy. By Frederick H. Hatch, Ph.D., F.G.S., of the Geological Survey of England and Wales. (London: Whittaker and Co., 1892.)

DR. HATCH has followed up the publication of his excellent "Introduction to the Study of Petrology," recently noticed in these pages, by a little book on mineralogy, which will, we think, be of equal service to students. He has recognized the fact that for one person who desires to enter upon a systematic study of mineralogy, regarded as a natural-history science, there are twenty who need only such an amount of mineralogical information as will enable them to profitably commence the study of geology. We think, therefore, that the prominent place given to the felspars, the pyroxenes, the amphiboles, the micas, and similar common rock-forming species in this work, is fully justified; and not less so the unsystematic but convenient grouping of other minerals as "ores and veinstones," "salts and other useful minerals," and "gems or precious stones." De Lapparent has indeed shown how a classification of minerals according to their mode of occurrence may be employed even in a systematic treatise; but Dr. Hatch's more humble attempt is not open to the criticism to which an ambitious work on the same lines would obviously be liable. It is clear that in a book of this kind there is not much scope for originality of treatment, but Dr. Hatch has admirably united brevity and clearness in his treatment of the crystallographical and physical characters of minerals. His method of giving the names and commonly employed reference letters to the crystal-combinations which he figures is well adapted to prepare the student for consulting larger treatises on the subject. So, too, the reference to the use of symbols, though it must evidently be very slight in a work of the dimensions of that before us, is eminently judicious. A short table of symbols of the chief forms belonging to each system, according to Miller and Naumann, will enable the beginner to recognize the meaning of all the very commonly occurring combinations; and it is clearly inexpedient to attempt more than this in such a very elementary work. We can confidently recommend the book as an excellent summary of mineralogical science, adapted to the wants of the geological student; and we believe the perusal of this small work may even be of advantage to those who desire to enter upon the more systematic study of the science of mineralogy. J. W. J.

To the Snows of Tibet through China. By A. E. Pratt, F.R.G.S. (London: Longmans, Green, and Co., 1892.)

The author of this book says in the preface that he has done his best "to withstand the temptation to generalize from limited experience, to which travellers in China seem peculiarly liable." Yet in his last sentence he expresses the opinion that several incidents he has mentioned "will show what a credulous and cowardly race the Chinese are." It ought surely to have occurred to him, when he set down this harsh and rather foolish judgment, that it was a striking example of the kind of generalization which he had wished to avoid. Fortunately the statement, although it seems to convey Mr. Pratt's final impression of the Chinese people, does not represent the general character of his work, in which scientific readers will find a good deal to interest them. He went to China in 1887 for the purpose of studying the natural history of the country, and remained until 1890, fixing his head-quarters at Ichang, a town on the left bank of the Yang-tze-Kiang, 1110 miles from its mouth. He crossed the frontier of Tibet, and at Ta-tsien-lu met Mr. Rockhill, whose excellent account of travels in Tibet we lately reviewed. Mr. Pratt worked hard in the various regions he visited, and collected many valuable specimens in several departments of natural history. He has not a very bright or attractive style, but many of his facts are themselves so interesting, and his enthusiasm as a collector is so keen and persistent, that there are few passages which his readers will desire to skip. In an appendix, Dr. Albert Günther gives a list of the species of reptiles and fishes brought by Mr. Pratt from the Upper Yang-tze-Kiang and the province Sze-chuen, with a description of the new species. There are also lists of birds and of Lepidoptera.

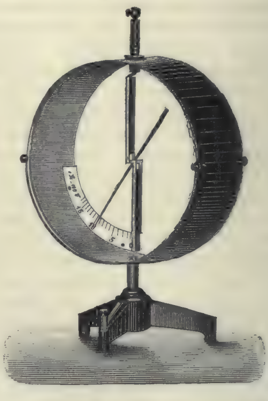
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Absolute Electrometer for Lecture Purposes.

I thought it might be welcome to some of your readers to be made acquainted with the following simple and cheap instruments which I have now used for some years with advantage in lectures, and also for many scientific purposes. They are electrometers, which are divided directly into volts. The needle, which is made of aluminium, moves about a horizontal axis of hard steel, and is repelled from the vertical brass piece connected with the knob above. The instruments have the advantage that they are much easier of manipulation than the gold-leaf electroscope, while the sensibility is nearly the same, and fully suffices for all lecture purposes. Potentials are read off directly in volts, so that the measurements in the experiments on electrostatics and electrodynamics can all be referred to the same unit, whereby the conception of the student gains in distinctness, and the lecture in simplicity. In consequence of the specially careful workmanship, the needle adjusts itself quickly and with certainty, so that readings may be made to about 10 volts. The back and front consist of glass disks 1 mm. thick, each of which covers a plate of zinc of the same size, out of which are cut two equal and opposite slits, through which the position of the needle on the brass scale is read off. The readings of the instrument are only correct when these plates are in position.

When the instrument is used in the lecture, the two plates are taken away, and the back glass plate covered with tissue paper, the instrument being illuminated from behind. The deflections are then easily visible in a room for more than a hundred students.



The method of graduation of these instruments I have described in full in *Wiedemann's Annalen*, vol. xliv., 1891, p. 771. They can be procured from the University mechanician here, Herr Albrecht, in three different sizes, 0–1500, 0–4000, and 0–10,000 volts. The first of these is the substitute for a gold-leaf electroscope. Herr Albrecht also makes the instruments for technical purposes. F. Braun.

Physical Laboratory, Tübingen, May 28.

Saturn's Rings.

The writer of the "Astronomical Column," in your number of June 2, directs attention to some observations of M. Bigourdan on certain peculiarities in the appearance of the following arm of Saturn's Rings observed by him on May 21. He mentions in particular a protuberance situated near Cassini's division. This, I think, is easily accounted for in a quite different manner. At 9h. 6m. p.m., according to Marth's ephemeris, two satellites, Enceladus and Tethys, were in conjunction with the east end of the ring. They were going in apparently opposite directions, Tethys away from Saturn. Their conjunctions with the middle of the Cassini division would, I find, take place at 8h. 36m. p.m. for Tethys, and at 9h. 36m. p.m. for Enceladus. Both satellites would be so close to the ring as to appear inseparable from it. Tethys, moving in an orbit inclined as much as 65′ to the plane of the rings, might easily be half superposed in appearance upon the *northern* boundary of the rings. The following remarks are from my observation-book of date May 21:—

"9h. 13·5m. G.M.T. The broadening of the east ansa near its end is probably due to Tethys and Enceladus being on opposite sides of it near its east end. 9h. 22m. The east ansa seemed a little longer than the west, perhaps due to Tethys now following it. Dione was seen close to the east end."

With the other observations and remarks of M. Bigourdan I quite agree. The straightening of the northern edge of both ansæ has frequently been noticed by me both before and after May 20. So lately as June 3 both ansæ seemed broadest at a distance of three-fifths of their length from the ball, and the following ansa was almost detached from the ball, partly by the shadow thrown by the ball on it, and partly by the more elevated part of the middle ring concealing all within it in the neighbourhood of the ball. A. FREEMAN.

Murston Rectory, Sittingbourne, June 6.

Aurora.

THE aurora of May 18 was seen here. I first noticed it at 11 p.m. (Dublin time), and watched it until 1 a.m., though I did not see either the beginning or the ending. It extended from west-north-west to north-north-east, and had a general altitude of 30°, though occasional streamers reached beyond Polaris. It was moderately bright, but certainly not brilliant, and showed no colour. About 12 o'clock horizontal streamers began to show themselves like electric search-lights, and continued for some time, their appearance being accompanied by a lengthening upwards of the radial streamers. The air was slightly hazy, and there was much stratus about, with detached masses of cumulo-stratus coming up from the west. Wind-force 3 of Beaufort's scale; barometer 30·05, stationary.

JAMES PORTER.

Crawford Observatory, Queen's College, Cork, May 31.

The Atomic Weight of Oxygen.

I NOTICE that Lord Rayleigh gives the following summary of results on the atomic weight of oxygen:—

Dumas	1842	15·96
Regnault	1845	15·96
Rayleigh	1889	15·89
,,	1892	15·882

showing the remarkable fact that the atomic weight has been steadily decreasing for the last fifty years. I would suggest, as the explanation of this, that the increased population of the world, together with the great consumption of coal, have caused great wear and tear of these atoms, so that they are now mostly deficient in weight. It would seem, in fact, desirable that a Congress of chemists should be called to consider the question of providing for the renovation of the oxygen supply, and issuing trustworthy atoms of the standard weight, 16, as sealed patterns.

ROBT. LEHFELDT.

Firth College, Sheffield, June 3.

The Nitric Organisms.

I AM most reluctant to occupy any of your space with a claim to priority. A statement made on p. 137 of your last issue can hardly, however, be allowed to pass without notice. Dr. P. F. Frankland states in his lecture at the Royal Institution that the possibility of the existence of a nitric organism was foreshadowed by himself, and that this hypothesis has recently been confirmed by Winogradsky. He then describes the method adopted by Winogradsky for separating the nitric from the nitrous organism, and the chemical properties of the former. The fact that the existence of a nitric organism was proved in the first instance by myself, its separation from the nitrous organism effected, and its chemical behaviour studied, before any publication on the subject by Winogradsky, is *entirely omitted!* Frankland's statement of the case is the more remarkable as Winogradsky frankly admits in his paper that our results were nearly the same, and that his were published subsequently to my own.

R. WARINGTON.

Harpenden, June 10.

Carnivorous Caterpillars.

EVERY experienced breeder of Lepidoptera knows to his, or her, cost that many caterpillars are either habitually, or casually, carnivorous and cannibalistic.

Useful hints on this subject are given in Dr. Knaggs' "Lepidopterist's Guide" (Gurney and Jackson).

Lewisham, June 13. R. McLACHLAN.

The Cuckoo in the East.

IN May 1887 I wrote to you that I had heard the cuckoo at Mussoorie. This year, on coming up here, I heard it at Doneira (about 2000 feet) and at Mamul (4000 feet). I have been here five days and have not heard it at all. There has been a deficiency of rain here, and it has been unusually hot. Both notes were very clear and distinct.

Dalhousie, May 22. F. C. CONSTABLE.

THE NEW LONDON UNIVERSITY.

WE have received for publication from the Association for Promoting a Professorial University for London the following proposals, adopted by the Association at a meeting held on Tuesday last:—

(1) It is desirable that there should, if possible, be one University in London.

(2) The objects of the University should be to organize and improve higher education and also to promote the advancement of science and learning.

It is desirable that the University be constituted on the following lines:—

(3) Subject to Clauses (9) and (12) the University to be governed by a Senate which shall ultimately consist of the Professors and a certain number of Crown nominees.

(4) The Professors to be nominated in the first instance by some independent authority, such as the Crown or the Commission contemplated in Clause (14), afterwards in such manner as the Senate may determine.

(5) The University to have power to absorb institutions of academic rank in London, which may be willing to be absorbed, due provision being made for protecting the interests of the teachers in such institutions, and for preserving the character of special trust-funds.

(6) The University to have the power of appointing Readers and Lecturers, either to supplement the teaching of the Professors, or to deliver graduation or other courses of lectures within the metropolitan area at such places as may be determined by the Senate.[1]

(7) The University to have power to grant degrees and to institute degree examinations. These examinations may, if found necessary, be different for those who have followed prescribed courses and for those who have not. Each Professor of the University to be *ex officio* an Examiner in the subject of his chair, but not necessarily to take part in every examination in that subject. Examiners, who shall not be Professors in the University, to be appointed by the Senate to take part in all degree examinations.

(8) The Professors, Readers, Lecturers, and other Teachers of the University to be grouped into Faculties, which shall have such consultative and administrative powers as shall be determined by the Senate.

---

[1] This side of the University work would probably include teaching of the following kinds:—

(*a*) Teaching, conducted in the University Buildings, supplementary to that of the Professors.

(*b*) Courses of instruction of a special or advanced character recognized by the University, *e.g.* of the type given by the German *Privat-Docenten*.

(*c*) Teaching of a more or less academic character conducted by lecturers appointed by the University at Institutions and Colleges, the objects or the standing of which render complete absorption into the University undesirable.

(*d*) Lectures at various local centres of the type known as "University Extension" lectures.

(*e*) Courses of lectures or occasional lectures by members of the University staff, or by other persons recognized by the University, for which a convenient centre might, with the co-operation of the Corporation of London and of the Mercers' Company, be found at Gresham College.

(9) The Body of Graduates in Convocation assembled to have the power of appealing to the Privy Council, but to have no veto upon the action of the Senate. The Chairman of Convocation to be *ex officio* a member of the Senate.

The Medical Schools will probably require special treatment. Though they might advantageously hand over the teaching of pure science to the University, each school might retain control over its own teaching of medicine and surgery and over the funds devoted thereto.

(10) The Medical Faculty to consist of representatives elected by the Teachers in recognized London Medical Schools.

(11) The recognized Medical Schools to be determined in the first instance by the Commission referred to in Clause (14), but afterwards from time to time by the Senate, subject to appeal to the Privy Council.

(12) A certain number of the members of the Medical Faculty to be nominated University Professors in accordance with the provisions of Clause (4). The number of Medical Professors on the Senate not to exceed one-fourth of the total number of University Professors on the Senate.

(13) A teacher of pure science in a recognized Medical School to become a Member of the Faculty of Science, whenever the appointment to his post is entrusted permanently or *pro hac vice* to the Senate of the University.

(14) To facilitate in the first instance the organization of the University, it is suggested that a small and independent Commission of legal and educational authorities be appointed by Act of Parliament with full powers—

(*a*) To investigate and determine upon the claims of institutions wishing to be absorbed under Clause 5.

(*b*) To arrange for the proper disposal of the trust-funds of those institutions which may be absorbed, and to determine the conditions under which their property shall be vested in the Governing Body of the University.

(*c*) To arbitrate on all matters concerning the interests of existing teachers as affected by the action of Clause (5), and

(*d*) Generally to make such arrangements as may be necessary for the establishment of the University on the foregoing lines.

We are requested to add that the names of those desirous of supporting the Association will be received by any member of the Executive Committee,[1] or may be sent directly to the Secretary (Prof. Karl Pearson, Christchurch Cottage, Hampstead, N.W.). The Association already numbers some seventy members, including Profs. H. E. Armstrong, F.R.S., W. E. Ayrton, F.R.S., F. O. Bower, F.R.S., O. Henrici, F.R.S., E. Frankland, F.R.S., E. Ray Lankester, F.R.S., F. Max Müller, O. J. Lodge, F.R.S., Norman Lockyer, F.R.S., W. J. Russell, F.R.S., W. A. Tilden, F.R.S., H. Marshall Ward, F.R.S., Principals H. R. Reichel, W. M. Hicks, F.R.S., and C. Lloyd Morgan, besides many other names equally well known in literature, science, and art. A complete list will shortly be issued.

SUBDIVISIONS IN ARCHÆAN HISTORY.[2]

I. *Subdivisions based on Kinds of Rocks.*

WERNER'S idea that kinds of rocks and grade of crystallization afford a basis for the chronological subdivision of crystalline rocks is more or less apparent in nearly all attempts that have since been made to lay down the general subdivisions of Archæan terranes. The "fundamental gneiss" has gone to the bottom and the thinner schists to the top. There is a degree of truth in the idea. But the assumptions are so great that at the present time little reason exists for the earnestness sometimes shown by advocates of such systems. The idea has little to sustain it in the known facts of geology. The following are sufficient to decide the question.

According to the thorough petrological and geological study of the rocks of the Bernardston region by Prof. B. K. Emerson [1]—a region in the Connecticut valley, in the towns chiefly of Bernardston, Massachusetts, and Vernon, Vermont—there are the following rocks: granite, largely feldspathic; dioryte, so like intrusive dioryte that it had been pronounced trap; quartz-dioryte; granitoid gneiss faintly foliated with biotite and passing into the granite; hornblende schist; quartzyte; quartzyte prophyritic with feldspar crystals; staurolitic and garnetiferous mica schist; hydromica schist; argillyte; massive magnetite, making a bed of magnetite rock; along with coarsely crystalline limestone and quartzytic limestone containing Crinoids, Corals, and Brachiopods: all together making one series of rocks of later Devonian age. My own observations in the region confirm the conclusions of Prof. Emerson. Such facts prove, moreover, that "massive" as applied to crystalline rocks does not signify *igneous*. The granite is not eruptive granite, but part of a stratum which is elsewhere quartzyte, the quartzyte graduating into granite; the latter was never in fusion.

Again: on the borders of New England and New York there are schists of all gradations from massive Cambrian gneiss to Cambrian and Hudson River hydromica schist and argillyte, the age fixed by fossils. Becker reports similar facts from the Cretaceous of California. Such observations, and others on record, make it hazardous to pronounce any gneiss in an Archæan area "fundamental gneiss," or any associated slaty schist the younger of the two. It may be true; but it may not be. It is probable that the thin-bedded schists are absent from the older Archæan, but not that the thick-bedded and massive are absent from the later Archæan.

The little chronological value of kinds of crystalline rocks in the later Archæan comes out to view still more strongly if we consider with some detail the length and conditions of Archæan time.

The earth must have counted many millions of years from the first existence of a solid exterior, when the temperature was above 2500° F., to the time, when, at a temperature below 1000° F.—probably near 500° F., supposing the atmospheric pressure to have then been that of 50 atmospheres—the condensation of the waters of the dense aërial envelope had made such progress that an ocean, moving in tides and currents, had taken its place on the surface.[2] There were other millions afterward along the decline in temperature to the 180° F. mark—180° F. the mean temperature of the ocean—when, according to observations on living species, the existence of plants in the waters became, as regards temperature, a possibility;[3] and still other millions from the 180° F. mark to that of 120° F., or nearly, when marine animal life may possibly have begun its existence. And since cooling went on at a decreasing rate toward the end, time was also long from the 120° F. mark to that of a mean oceanic temperature of 90° F., or below it, when Paleozoic life found congenial conditions in the water. The mean temperature now is about 60° F.

---

[1] This Committee at present consists of the following:—F. V. Dickins, G. Carey Foster, R. S. Heath, E. Ray Lankester, Karl Pearson, H. E. Roscoe, A. W. Rücker, T. E. Thorpe, W. C. Unwin, W. F. R. Weldon.

[2] Reprinted from the June number of the *American Journal of Science*, rom advance sheets forwarded by the author. The paper is to be continued in the *American Journal of Science*.

[1] A description of the "Bernardston Series" of Metamorphic Upper Devonian Rocks, by Ben K. Emerson, *American Journal of Science*, III., xl., 263, 1890.

[2] R. Mallet estimated, in view of the density of the atmosphere—over 200 atmospheres to the square inch—that the first drops of water may have been condensed on the earth's surface when the temperature was that of molten iron.—*Phil. Mag.*, January 1880.

[3] They live now in waters having a temperature of 200° F., Brewer, at Pluton Creek, California; 185°, W. H. Weed, Yellowstone Park. Moreover germs of Bacilli have germinated after having been boiled for an hour.

The ocean, sooner or later after its inaugural, began the work of making permanent sediments, that is sediments that were not speedily recrystallized; and these sediments, through the millions of years that followed, must have been of all kinds and of great thickness.

The conditions became still more like the present after the introduction of life with the further decline of temperature. Even before its introduction, iron oxides, iron carbonate, calcium carbonate, calcium-magnesium carbonate, and calcium phosphate had probably commenced to form, for the atmosphere, although it had lost the larger portion of its water-vapour, still contained, as writers on the "primæval earth" have stated, the chief part of its carbonic acid, amounting to all that could be made from the carbon of the limestones, coal and carbonaceous products now in the world. It had also a great excess of oxygen—all that has since been shut up in the rocks by oxidations. And these most effectual of rock-destroying agents worked under a warm and dripping climate.

The amount of carbonic acid, according to published estimates, has been made equivalent in pressure to 200 atmospheres, or 3000 pounds to the square inch. 200 is probably too high, but 50 atmospheres, which is also large, is perhaps no exaggeration. Hence, the destruction of rocks by chemical methods must have been, as Dr. Hunt and other writers have urged, a great feature of the time; and long before the introduction of living species, the temperature had so far declined that the making of silicates must have given way in part to the making of deposits of carbonates and oxides.

But with the existence of life in the warm waters, through the still later millions of years, there should have been, as Weed's study of the Yellowstone Park has rendered probable, abundant calcareous secretions from the earliest plants, and, additions later, through the earliest of animal life. Great limestone formations should have resulted, and large deposits of iron carbonate, and perhaps iron oxides, over the bottom-sediments of shallow inland or sea-border flats, besides carbonaceous shales that would afford graphite by metamorphism.

In fact, long before the Archæan closed, the conditions as to rock-making were much like those that followed in the Paleozoic. Surely, then, all attempts to mark off the passing time by successions in *kinds* of rocks must be futile. Some *varieties* of the various kinds of rocks are probably Archæan only; but not all those of its later millions of years. Even crystalline and uncrystalline may not be a criterion of chronological value. The beds of the Upper Archæan, under the conditions existing, may well, over some regions, be uncrystalline still, and may include carbonaceous shales that hold to this time their carbonaceous products. Such uncrystalline beds may now exist over the Continental Interior; for the great Interior has generally escaped when metamorphic work was in progress on the Continental borders.

The amount of carbonic acid is most readily estimated by first obtaining the probable amount for all post-Archæan sources, and then adding to this that which is indicated by Archæan terranes. The calculation is here given in detail that others may use it for deductions from other estimates.

For the estimation there are the following data. A cubic foot of pure limestone which is half calcite and half dolomite and has the normal specific gravity 2·75, weighs 171·4 pounds; and this, allowing for $\frac{1}{12}$th impurity, becomes 157 pounds and corresponds to 72 pounds of carbonic acid. A cubic foot is equal to an inch-square column 144 feet in height. Since 72 is half of 144, each foot of the column of such limestone contains half a pound of carbonic acid. Hence a layer of the limestone one foot thick would give to the atmosphere, on decomposition, half a pound of carbonic acid for each square inch of surface.

A foot layer of good bituminous coal containing 80 per cent. of carbon, $G=1·5$, will give to the atmosphere by oxidation 1·9 pounds of carbonic acid per square inch of surface.

If the mean thickness of the limestone over the whole earth's surface, that of the oceans included, reckoned on a basis of $\frac{1}{12}$th impurity, is 1000 feet, the contained carbonic acid amounts according to the above to 500 pounds per square inch, or 34 atmospheres (of $14\frac{3}{4}$ pounds), and if the mean thickness of the coal is one foot, the carbonic acid it could contribute would be 1·9 pounds per square inch. Adding these amounts to the carbonic acid corresponding to the carbon in the mineral oil and gas and other carbonaceous products of the rocks and organic life, supposing it to be six times that of the coal, the total is 513·5 pounds, or 35 atmospheres. The mean thickness of Archæan calcium, magnesium, and iron carbonates is not a fourth of that of post-Archæan. Estimating the carbonic acid they contain and that corresponding to the graphite of the rocks at ten atmospheres, the whole amount becomes 45 atmospheres.

To bring the amount up to the estimate for early Archæan time of 200 atmospheres of carbonic acid, the mean thickness of the limestone for Archæan and post-Archæan time should be taken at nearly 6000 feet.

Part of the limestone of post-Archæan terranes was derived from the wear and solution of Archæan limestones, iron carbonate, &c., and hence all the 35 atmospheres to the square inch were not in the atmosphere at the commencement of the Paleozoic. But if we reduce the 35 atmospheres, on this account, to 25 atmospheres, it is still an enormous amount beyond what ordinary life, even aquatic life, will endure. Reducing the estimated mean thickness for the limestone layer over the globe from 1000 to 500 feet would make the amount nearly one half less.[1]

The making of carbonates early began the work of storing carbonic acid and purifying the atmosphere; and the introduction of life increased the amount thus stored, and added to it through the carbonaceous materials from living tissues contributed to the earthy deposits. But with all the reductions that can be explained, the excess is still very large. It has been proved by experiment that an excess also of oxygen diminishes the deleterious influence of carbonic acid on plants; and that if the amount of this gas is made equal to that of the oxygen in the present atmosphere, plants will still thrive. How far this principle worked in early time cannot be known.

2. *Subdivisions based on Stratification.*

The stratification in an Archæan region affords the only safe and right basis for subdivisions. This method has been used in the separation of the Huronian from the older Archæan; and recently, with good success, by Irving and Van Hise in the study of the Penokee-Marquette region, or the Huronian belt of Wisconsin and Michigan. The intimate relation of the beds in the series has been worked out and their unconformability with the lower rocks thus ascertained, besides the stratification and constitution of the iron-ore series within the belt. This is the first step toward that complete study which should be carried on throughout all Archæan areas, however "complex." The distribution of the rocks and their apparent or real stratigraphic succession, whether massive or schistose, the positions of the planes of foliation or bedding, the unconformities in superposition, and those of mere faulting, and all structural conditions, should be thoroughly investigated. Correlation by likeness of rocks has its value within limited areas, but only after much questioning.[1] The work is easy in its methods, yet perplexing because in North America the uplifts and flexures of different periods have in general taken place in parallel directions, so that unconformabilities are disguised, especially when the two formations are nearly alike in grade of metamorphism. Follow along the overlying to places where its metamorphism is of low grade, and there may be success.

---

[1] A right estimate is very desirable. If made for North America, it could not be far out of the way to assume it to be a mean for like areas of the other continents as regards the limestone. But with the best possible result for the continents, the oceanic area, three times that of the continents, and out of the reach of investigation as to depths of bottom deposits, remains a large source of doubt.

There is a first point of special importance to be accomplished by Archæan investigation. The Huronian of the Penokee-Marquette region is partially metamorphic. To the east, the iron ore, according to the describers, is mainly metamorphic magnetite and hematite; to the west, especially in the Penokee region, it is largely iron carbonate, or the ore in its original state. Other facts show a diminishing grade of metamorphism to the westward. In the Penokee district, the ore is underlain by a bed of "cherty limestone," the chert of which, like the interlaminated jasper of the iron ore bed, is regarded by Van Hise as probably of organic origin, like later chert. It has among the overlying beds carbonaceous shales containing, according to Chamberlin, 40 per cent. of carbon, bearing thus evidence of very large organic carbonaceous contributions when in process of formation. The great beds of iron ore, the upward gradation eastward in metamorphism, the relations in position to the admitted Archæan adjoining it on the south, seem to prove the Huronian series to be Upper Archæan, as it has been generally regarded, but in a non-metamorphic and partially metamorphic condition. The question thence arises: Are the ore-bearing rocks of the Archæan of Eastern Canada, New York, New Jersey, and other parts of the Appalachian chain, Huronian in a state of *high-grade* metamorphism? Are the chondroditic limestones, which, in some localities, occur in and with the ore, part of the Huronian formation? Does the eastern iron-bearing series rest unconformably on inferior Archæan?

The *Algonkian* (or Agnotozoic) beds belong either to the Archæan or to the Paleozoic.

The Archæan division of geological time is of the same category with the Paleozoic, Mesozoic, and Cenozoic; all are grand divisions based on the progress of life, and they include together its complete range. There is no room for another grand division between Archæan and Paleozoic any more than for one between Paleozoic and Mesozoic. In contrast, the Algonkian division is not above the Cambrian in grade, it being based on series of rocks. Its true biological relations are in doubt, because fossils representing the supposed life of the period are unknown, or imperfectly so. The discovery in any rock so-called of Trilobites, Crustaceans, Mollusks, Brachiopods, or Crinoids, whatever the species, would entitle such rocks to a place in the Paleozoic, and either within the Cambrian group or below it. Walcott has already reported such fossils from the beds at the bottom of the Colorado cañon referred by him to the Algonkian—namely, besides a Stromatoporid, a small Patella-like or Discina-like shell, a fragment of a Trilobite and a small Hyolithes—forms which make the beds Paleozoic beyond question.

3. *Subdivisions based on Physical and Biological Conditions.*

Although the physical and biological conditions of the early globe are within the range of observation, there are generally admitted facts which afford a basis for a philosophical division of the time; and from it geology may derive instruction. The subdivisions to which we are led are the following:—

I. The ASTRAL æon, as it has been called, or that of liquidity.

II. The AZOIC æon, or that without life.

(1) The *Lithic era*, commencing with completed consolidation: the time when lateral pressure for crust-disturbance and mountain-making was initiated, and when metamorphic work began.

(2) The *Oceanic era*, commencing with the ocean in its place: oceanic waves and currents and embryo rivers beginning their work about emerged and emerging lands, and the tides, the retarding of the earth's rotation.

III. The ARCHÆOZOIC æon, or that of the first life.

(1) The *era of the first Plants*: the Algæ and later the aquatic Fungi (Bacteria); commencing possibly with the mean surface temperature of the ocean about 180° F.

(2) The *era of the first Animal life*: the Protozoans, and forms related to the embryos of higher invertebrate species; commencing possibly with the mean surface temperature of the waters about 120° F., and ending with 90° F. or below.

The subdivisions, as is evident, mark off great steps in the progress of the developing earth, although the rocks bear no marks of them that can be distinguished.

The Huronian period covered, probably, much of Archæozoic time; and this is all in the way of correlation that can be said. It is well to note here that if the Eozoon is really animal in origin, the "Laurentian" rocks of Canada in which it occurs must be Huronian, or the later of Archæan terranes.

Respecting the Oceanic period it is observed above, "*commencing with the ocean in its place.*" It appears to be almost a physical necessity that the oceanic depression should have been made in the first forming of the solid crust, if the globe cooled to the surface from the centre outward; that is, unless a liquid layer remained long afterward beneath the crust.

The depression was certainly made long before the close of Archæan time. For the enormous amount of rock-making of the Archæan over the continent implies the existence of emerged rocks with reach of the decomposing, eroding, and denuding agencies of the atmosphere and atmospheric and oceanic waters. A submergence in the ocean of 50 feet is almost a complete protection against mechanical and chemical wear. Moreover North America has its Archæan lands not only in the great nucleal mass, 2,000,000 square miles in area, but also in the series of Archæan ranges parallel to the outlines of the nucleus, which extend eastward to the eastern limit of Newfoundland, and westward to the Pacific. And it has correspondingly shallow-water Cambrian deposits lying between these ranges from Eastern Newfoundland and the coast-region of New Burnswick and Massachusetts, westward across the continent about most of the Archæan outcrops, to within 300 to 400 miles of the Pacific Ocean, as shown by Walcott.

There is hence reason for the conclusion that, at the close of Archæan time, the continent of North America was present not merely in outline, but also in general features, and at shallow depths where not emerged.

This fact with reference to North America means much. It means that by the end of Archæan time, the continents generally were essentially in a like condition—outlined and at shallow depths where not emerged; that, therefore, the oceanic depression was then large and deep enough to hold the ocean. Further, this last fact indicates, if the mean level of the continents was coincident with the water's surface, that the oceanic depression had already a depth of 12,000 feet, or that of the present mean depth of the waters; and that the lowering, through later time, of the bed 1500 feet on an average (or 2000 feet according to other estimates) would give the continents their present mean height. And it is a fact of deep geogenic significance, that nearly 1000 feet of this mean height was received after the beginning of the Tertiary.

---

[1] As a preliminary in the study of any such region, thousands of dips and strikes of planes of foliation or bedding should be taken (in imitation of Percival's work before 1842, mentioned in the note on p. 440 of the last volume of the *American Journal of Science*), and all should be plotted on maps of large scale by means of symbols with affixed numbers recording the dips and strikes, for full comparison in the final elaboration. Even the Penokee-Marquette region needs further investigation with a clinometer-compass in hand

Before commencing the study of any crystalline rocks, models of flexures should have been studied until the fact is fully appreciated that a flexure having an inclined axis—the commonest kind—ranges through 180°, or nearly, in its dips and strikes, and until the characters of the bedding in different transverse sections of flexures are well apprehended. A good model for studying flexures may be made from a cylindrical stick of coarse-grained wood having the bark on (if of a smooth kind); it may be about four inches in diameter and twelve to fifteen long. Draw a straight line through the centre of one end; and from this line saw across obliquely to the edge at the opposite end. After planing smooth the sawed surface, the layers of the wood may then be coloured by groups; and three colours, or two besides that of the wood, are better than more. The model of a flexure having an inclined axis is then complete. Cross-sections of the model may be cut and the colours added to the new surfaces. For models of overthrust flexures, this method is not practicable, as wood of elliptical section would be required. They may be made of paper-pulp of three colours.

JAMES D. DANA.

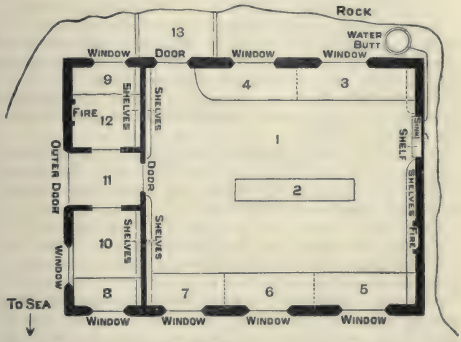
OPENING OF THE LIVERPOOL MARINE BIOLOGICAL STATION AT PORT ERIN.

THE Liverpool Marine Biology Committee, which commenced the investigation of the fauna and flora of Liverpool Bay and the neighbouring seas seven years ago, and has kept up a small biological station on Puffin Island, Anglesey, for the last five years, passed on Saturday (June 4) into a new phase of its existence, and, it may be hoped, a more extended sphere of labour, when His Excellency Spencer Walpole, Lieutenant-Governor of the Isle of Man, declared the new marine laboratory at Port Erin to be open for work. The Puffin Island establishment has been very useful to the Committee, and well worth the small annual expenditure required for its modest outfit. It has been used by a few students who wished to gain a general knowledge of the common marine animals and plants in a living state, and by a limited number of specialists who went there to make observations, or who had the material for their investigations collected there and sent to them. But the Committee has felt for the last year, at least, that a station which was more readily accessible from Liverpool, and with hotel or lodging accommodation obtainable on the spot, would enable their members to do more work, and be of more use both to students and to investigators. Also, it was evident that after five years' work on the shores of the small island the greater number of the plants and animals had been collected and examined, and that a change to a new locality with a rich fauna and a more extended line of coast would yield increased material for faunistic work. On looking round the Liverpool Marine Biology Committee's district, Port Erin, at the southern end of the Isle of Man, at once presented itself as the best available place.

From its position, and the shape of the land, Port Erin has within a distance of a couple of miles in three directions—to Fleshwick Bay, to the Calf, and to Port St. Mary—a long and varied coast-line, with a number of small bays, furnishing good collecting-ground and shallow-water dredging. Two of these bays, Port Erin and Port St. Mary, have harbours with sailing-boats, and face in nearly opposite directions, so that in most winds one or other is sheltered and has a quiet sea. The rich fauna around the Calf and off Spanish Head is within easy reach: at a distance of three to four miles from the laboratory are depths of 20 to 30 fathoms, and at fourteen miles 60 to 70 fathoms. Although it is a considerable distance from Liverpool, still it is reached by a regular service of swift steamers and convenient trains, so that there is no uncertainty or delay in the journey.

The plan of Port Erin shows the position and surroundings of the Biological Station. It is on the beach at one corner of the bay, near where the sand and rocks join, and at the foot of the cliff upon which the Bellevue Hotel stands. It is connected with the road by means of a winding gravel path and steps, and is about a third of a mile from the railway station. It is just at the bottom of the hotel grounds, and arrangements have been made with the proprietor by which those working at the Biological Station can live comfortably and economically at the hotel. The sea comes to within a few yards of the windows, and the bay immediately in front is sheltered pure sea-water with a varied bottom, suitable for small boat dredging and tow-netting; while the rocky coast, extending out towards Bradda Head, has many creeks and good shore pools.

The station is a substantially built, three-roomed house, measuring a little over 30 feet by 20 feet, and standing on a solid stone and concrete platform, which raises it about 10 feet above high tide. It has windows looking out in three directions, north, south, and west. The front door leads into a passage, from which open to right and left two small rooms, which can be used as the Director's room and the Secretary's office, and will also be available for the use of members of the Committee, or any special students who require a separate room for their work. Opposite the entrance is the door into the main laboratory, which measures about 22 feet by 20 feet, and has windows on both sides. In front of the windows run strong fixed work-tables, which will accommodate five students with ease. At the ends of the room are fire-place, sink, tables, bookcase, and abundance of shelving, while along the centre runs a strong table for small aquaria and vessels containing animals. A door in one corner opens into a useful small yard between the house and the cliff, in which the concrete fresh water cistern is placed, and where dredges and other implements can be stored.



Plan of the Liverpool Marine Biological Laboratory at Port Erin. 1, Main laboratory (22 × 20), with work places for five students; 2, strong table for aquaria; 3 to 9, tables; 10, small laboratory for Director or members of Committee; 11, passage; 12, small laboratory or Secretary's office; 13, small yard.

The Liverpool Salvage Association had kindly promised to lend their useful steamer, the *Hyæna*, to the Committee for four or five days at the time of opening; but as she was called off on duty at the last moment, they sent the steamer *Mallard* instead, on Friday afternoon, across to Port Erin, where she remained until Monday. Dredging trips in the neighbourhood took place on three of the days, and on Saturday evening tow-netting with submarine electric lights was carried on after dark in the bay.

At one o'clock on Saturday the Lieutenant-Governor, the Bishop, the Manx Attorney-General, and a number of members of the House of Keys, and others, arrived at Port Erin, where they were met by Prof. Herdman, Mr. I. C. Thompson, Mr. A. O. Walker, Mr. J. Vicars, Sir James Poole, and others of the L.M.B.C., along with some biologists from elsewhere, the Liverpool party numbering over thirty. The Governor was conveyed to the front of the Biological Station, where, after being presented by Prof. Herdman with the reports upon the fauna of Liverpool Bay published by the L.M.B.C., he declared the building open for work, and then the party entered and proceeded to examine the results of the forenoon's dredging, laid out in dishes and under microscopes. At two o'clock the Governor and the Bishop were entertained to luncheon at the Bellevue Hotel by the L.M.B.C., Prof. Herdman being in the chair, with the Governor on the right and the Bishop on the left. Mr. I. C. Thompson, Hon. Sec. L.M.B.C., occupied the other end of the table, and about seventy in all sat down to luncheon, including the President and Secretary and some other members of the Isle of Man Natural History Society. The Governor proposed the toast of "The Liverpool Marine Biology Committee," to which Prof. Herdman replied.

The whole of the following day was spent in dredging and tow-netting from the *Mallard* to the west and south of Port Erin at the following localities:—

(1) 3 miles west of Fleshwick: 20 fathoms, 6 hauls of dredge: good varied ground, old shells, &c.

(2) 14 miles west of Dalby: 60 fathoms, 2 hauls; sticky clay mud, with few animals.

(3) 8 miles west of Fleshwick: 33 fathoms, 3 hauls.

(4) 6 miles west of Port Erin: 24 fathoms, 2 hauls.

(5) 1 mile west of Calf: 20 fathoms, 2 hauls.

(6) Off Kitterland, Calf Sound: 17 fathoms, 1 haul.

At each of these localities, besides the ordinary large dredge, tow-nets were used, and also Mr. Walker's small dredge with a canvas bag for bringing up samples of the bottom to be washed for small Crustacea, &c.

On the following day (June 6), on the way back to Liverpool, dredging from the *Mallard* was conducted at the following places:—

(1) 20 miles south-east from Port St. Mary: 26 fathoms.

(2) 25 miles south-east from Port St. Mary: 23 fathoms.

Both of these localities were good productive ground, and large hauls were obtained.

(3) 20 miles north-west from the Bar: 18 fathoms.

(4) 15 miles north-west from the Bar: 16 fathoms.

On all these occasions, besides the surface tow-nets, a bottom tow-net was attached a little way in front of the dredge, and appeared to work well; its contents were usually a good deal different from those of the surface nets.

Amongst the forms dredged in these two days were:—*Clathria seriata*, *Spongelia fragilis*, *Sarcodictyon catenata*, *Palmipes membranaceus*, *Stichaster roseus*, *Porania pulvillus*, *Antedon rosaceus*, *Adamsia palliata*, *Crania anomala*, *Pandora inæquivalvis*, *Cynthia echinata*, and the rare little Ascidian *Forbesella tessellata*, and a large number of other species, representing most of the invertebrate groups, which have not yet been sorted out and identified. A list of the species previously found in the neighbourhood of Port Erin will be found in "Fauna of Liverpool Bay," vol. i. pp. 318–41.

The Liverpool Marine Biology Committee's Station at Port Erin is now open, and is provided with a few microscopes, microtome, ordinary reagents, dishes, &c. Any biologists wishing to go there for collecting or other work are requested to apply for particulars to Prof. Herdman, or to Mr. I. C. Thompson, 4 Lord Street, Liverpool.

THE ANNUAL VISITATION OF THE GREENWICH OBSERVATORY.

THE report of the Astronomer-Royal to the Board of Visitors this year commences with a reference to the loss sustained by the Observatory by the death of Sir G. B. Airy, who for sixty years was closely connected with the working of this institution.

As regards the buildings, that of the south wing of the proposed Physical Observatory has been authorized by the Admiralty, considerably more space being required for the storing of chronometers and deck watches. The buildings of the three other wings and the two upper stories of the central tower have, for the present, been laid aside, sufficient provision not being made for them in the present financial year. The new 36-foot dome, which is being provided for the efficient working of the 28-inch refractor, is still in course of erection, while the pair of semi-domes for the Transit Pavilion in the Front Court has been found to be quite satisfactory. The electric light installation, which has in a former report been suggested by the Astronomer-Royal for the photographic equatorial and for other instruments, has been sanctioned by the Admiralty, and will, during the course of the present year, be provided. The advantages of such a means of lighting will at once make themselves apparent, for by the old method the storage cells had to be charged from primary batteries.

The Observatory, by the will of the late Sir George Airy, has had several valuable works bequeathed to it. Mr. Wilfred Airy has as yet transferred 94 volumes and 134 unbound tracts, which will form a valuable addition to the library, together with the manuscript containing the calculations of Sir George Airy's numerical lunar theory. His bust, by Foley, has also been received and is now placed in the Octagon Room.

With regard to the work done with the transit-circle, the number of observations was not so great as in former years, as the object-glass was removed for repolishing on August 10 to October 5. The definition and colour-correction of this glass has been greatly improved by Mr. Simms. New steel screws to the R.A. and Z.D. micrometers were added at the same time, and the wire system also received a slight modification. The wires are ten in number, distant from each other by exact multiples of a screw-revolution, and so arranged that the mean of the ten nearly coincides with one of them. A little computation is thus saved in taking the mean of a transit, and the only thing lost is symmetry in the arrangement.

During the rest of the year the sun, moon, and planets have been regularly observed on the meridian as before:—

Transits, the separate limbs being counted as separate observations	4801
Determinations of collimation error	249
Determinations of level error	335
Circle observations	4463
Determinations of nadir point (included in the number of circle observations)	319
Reflexion observations of stars (similarly included)	436

The annual catalogue of stars observed in 1891 contains 1813 stars.

The results from the observations for the determination of variation of personal equation with stellar magnitude, indicated that there was a general tendency with all the observers to observe stars later when the light was diminished by placing a gauze screen before the object-glass; but it was stated that "it is not clear that we are here measuring a real change of personal equation in observations of fainter stars, as the introduction of the screen modifies the image of the star, and this modification of the image may give rise to a change of personal equation unconnected with the diminution of brightness."

It is noted that as the external thermometer rises there is a nearly uniform decrease of the readings of the internal thermometers over that of the standard exterior thermometer, the excess vanishing at something over 70°. This is accounted for by the variation of the temperature of the walls of the room, the permanent temperature of which is always slowly changing.

The total number of observations made with the altazimuth in the year ending 1892 May 10 is as follows:—

Azimuths of the moon and stars	345
Azimuths of Mark I.	162
Azimuths of Mark II.	182
Zenith distances of the moon	166
Zenith distances of Mark I.	164
Zenith distances of Mark II.	176

These numbers are slightly greater than in recent years, owing to the fact that during August and September, when the transit-circle was under repair, the observations of the moon with the altazimuth were made throughout the lunation instead of being confined to the first and last quarters.

With regard to clocks and chronographs, we may mention that the daily rate of the sidereal standard clock underwent a very considerable disturbance, changing from a daily gain of 1·0s. to that of 2·0s. The cause of this difference was due to some workmen who were fixing a new shelf, the necessary hammering setting up vibrations in the building.

With the reflex zenith tube, eighteen double observations of γ Draconis have been made, but owing to the pressure of work the reductions are not yet complete.

Ten occultations of stars by the uneclipsed moon (8 disappearances and 2 reappearances) and 48 phenomena of Jupiter's satellites have been observed with the equatorials, or with the altazimuth. These observations are completely reduced to 1891 December 31. On the occasion of the partial eclipse of the moon on 1892 May 11, 7 disappearances and 3 reappearances were observed of the faint stars in a list prepared by Mr. Crommelin; and the times of transit of the shadow over some principal craters were also noted. But it is to be regretted that, although favoured by fine weather on this occasion, the Observatory was seriously crippled in their instrumental equipment, the 13-inch refractor of the south-east equatorial and the Lassell 2-feet reflector being both dismounted.

With the photographic equatorial, 301 plates with a total of 1190 exposures have been taken on 112 nights, many of these being taken for special investigations. Of these, 62 plates were taken to determine the relations between diameter of image, length of exposure, and brightness of the star, the results of which have already appeared in the *Monthly Notices* for January of this year. The discussion indicated that, through a range of exposures corresponding to 8 magnitudes, "the square root of the diameter increases as the logarithm of the exposure; and further, that for equal photographic effects duration of exposure should vary inversely as the brightness of the star." These results were based on as many as 2200 measures of 150 star images. The *réseaux* seem to have given much trouble, the silver film developing pin-holes, the images of which resemble on the photographic plates those of stars. M. Gautier is now supplying the Observatory with two more, coated this time with a film of collodion, in the hopes that it may be freed from the deficiencies mentioned above. The catalogue which has been undertaken at Greenwich of the guiding stars for the zones + 60° to the pole, + 25° to + 29°, and − 3° to − 5°, is very near completion. The catalogues of places (epoch 1900) are complete for the Greenwich zones + 65° to + 80° (the reductions for the circumpolar region being deferred), also for the zones + 60° to + 64° to be photographed at Rome, and for the Oxford zones + 25° to + 29°. The stars for the San Fernando zone (− 3° to − 5°) have all been selected, and their places have been computed for those between R.A. 12h. and 18h.

Spectroscopic and Photographic Observations.—The observations of the displacement of the lines in stellar spectra for the determination of their motion in the line of sight have not this year been regularly continued; a preliminary discussion of the former observations suggesting that they were affected to some extent by the position of the spectroscope, Vega and Altair were observed during the summer and autumn at as wide a range of hour-angle as possible, and with the spectroscope set to each of the four positions 0°, 90°, 180°, and 270°; the slit being parallel to the declination circle at 0°. The numbers of observations obtained of the F line in the spectrum of Vega are: at 0°, 39; at 90°, 42; at 180°, 36; and at 270°, 39; and of the F line in the spectrum of Altair: at 0°, 30; at 90°, 32; at 180°, 26; and at 270°, 29. The measures are now under discussion, and give clear indications of the existence of the systematic error referred to. The observations were interrupted by the dismounting of the 12¾-inch telescope on 1891 November 19.

At the appearance of the new star in Auriga the south-east equatorial was unfortunately dismounted, but the object-glass presented to the Observatory by Sir Henry Thompson was mounted as quickly as possible on the Thompson telescope; but alterations of the telescope tube were found necessary to bring the spectrum to focus on the photographic plate, and before these could be completed, the Nova had become nearly too faint for observation.

For the year 1891, 360 out of 365 photographs of the sun's surface have been selected for measurement; 136 of these were sent to the Solar Physics Committee from India and Mauritius.

The solar activity has increased in a remarkable manner during the past year. While there were 175 days without spots in the year 1890, there were only 21 such days in 1891, and since 1891 March 28, the sun has not been free from spots on a single day on which it has been observed. The number of groups visible on the disk at the same time, and their average size and complexity, have all greatly increased during the past twelve months, the group of February 5–18 being the largest ever photographed at Greenwich. This group has had an unusually long life, appearing first on 1891 November 15, and persisting till 1892 March 17.

Magnetic Observations.—The continuous register by photography of the magnetic elements has been satisfactorily maintained. It has been found that serious disturbances of the earth-current registers is due to the trains of the City and South London Electric Railway, situated at a distance of 2½ miles from the nearest earth plate, and about 4½ miles from the Observatory. The change of potential takes place every two or three minutes, varying in amount from "a small fraction of a volt to one-third of a volt or more."

The following are the principal results for the magnetic elements for 1891:—

Mean declination (approximate)	17° 23′ West.
Mean horizontal force ...	3·9587 (in British units). 1·8253 (in Metric units).
Mean dip	67° 19′ 49″ (by 9-inch needles). 67° 21′ 0″ (by 6-inch needles). 67° 23′ 22″ (by 3-inch needles).

In the year 1891 there were five days of great magnetic disturbance, but there were also about twenty other days of lesser disturbance, for which tracings of the photographic curves will be published; these days having been selected in concert with M. Mascart according to the arrangement mentioned in the last report. The calculation of diurnal inequalities from five typical quiet days in each month, commenced in 1889 at Prof. Rücker's suggestion, has been continued.

From February 13 to 14 a very large disturbance was recorded, commencing a day after the large sun-spot was on the central meridian. Considerable magnetic disturbances also occurred on March 6, 11, and 12. Other disturbances occurred on 1891 September 9, 1892 April 25–26 and May 1, and may perhaps "be connected with spots then on the sun's disk."

Meteorological Observations.—The mean temperature of the year 1891 was 48°·4, being 1°·1 below the average of the fifty years, 1841-1890. The highest air temperature in the shade was 85°·1 on July 17, and the lowest 12°·0 on January 10. The mean monthly temperature in 1891 was below the average in all months excepting June, September, October, December. In January it was below the average by 4°·4, in April and August by 3°·0, and in May by 2°·8.

The mean daily motion of the air in 1891 was 278 miles, being 4 miles below the average of the preceding twenty-four years. The greatest daily motion was 960 miles on December 10, and the least 34 miles on February 23 and 24. The greatest pressure registered was 31·5 lbs. on the square foot on November 11. On December 10 the pressure plate was not in action.

The number of hours of bright sunshine recorded during 1891 by the Campbell-Stokes sunshine instrument was 1222, which is about 66 hours below the average of the preceding fourteen years, after making allowance for difference of the indications with the Campbell and Campbell-Stokes instruments respectively. The aggregate number of hours during which the sun was above the horizon was 4454, so that the mean proportion of sunshine for the year was 0·274, constant sunshine being represented by 1.

The rainfall in 1891 was 25·0 inches, being 0·5 inches above the average of the preceding fifty years.

Chronometers, Time Signals, and Longitude Operations.—The number of chronometers and deck watches now being tested at the Observatory is 157 (91 box chronometers, 19 pocket chronometers, and 47 deck watches). The annual competitive trial of chronometers commences on July 2, and the trial of deck watches on October 22.

In the year ending 1891 May 10, the average daily number of chronometers and deck watches being regularly rated was 243, the total number received was 765, the total issued 750, and the number set to repair 442.

At the annual trial of chronometers the performance was good, the average trial number of the first six was 21·4, which compares favourably with those of previous years.

The dropping of the time-balls is next referred to. The Greenwich one was not raised on October 14, December 10 and 13, 1891, owing to the violence of the wind; on April 1, 1892, the springs of the mean solar clock failed to act, and on October 19 and November 22 failure in the connections was the cause.

The return signal from Deal was interrupted last November several times, owing to an accumulation of grease which had been applied to the piston. Signals from Devonport clock failed on 51 days, and those from the Westminster clock on 14 days.

The publication of the observations for the Paris-Greenwich longitude in 1888, and of those for the Dunkerque-Greenwich longitude in 1889, has been delayed pending a redetermination of the former longitude which was commenced on June 6 of the present year; and it is hoped to settle several questions of importance raised by the discussion of the results obtained in 1888.

The first stage of the operations for the longitudes Montreal-Canso-Waterville-Greenwich was completed on May 23. The time of transmission along the cable Waterville-Canso was about a quarter of a second—a result confirmed by a rough comparison of signals on 1892 May 11. Prof. McLeod, of Montreal, paid a similar preliminary visit to Canso in 1891 June, and found an accordant value for the time of transmission. Four portable transits were used for the time determinations. These latter were made in all on 14 nights at Greenwich, 12 at Waterville, and about the same number at Canso and Montreal. The preliminary reduction gives every promise of satisfactory accuracy at Greenwich and Waterville.

Captain Grant, R.E., has been at work at the Observatory practising the requisite transit observations for determining the boundary of Mashonaland.

In the Astronomer-Royal's general remarks at the conclusion of his report, he refers to a plan he has devised for making observations out of the meridian with a transit-circle. He proposes to have it so constructed that by means of a turn-table it can be placed and firmly fixed in certain definite azimuthal, the instrument "being used essentially as a transit-circle for a complete series of observations in the selected azimuths plane." This instrument, as he says, would advantageously replace the existing altazimuth, and could be used "not only for the important object of making extra-meridian observations of the moon but also for observations of the sun, planets, and stars (in the meridian as well as out of the meridian), for the elimination, as far as practicable, of systematic errors, and for the more accurate determination of astronomical constants." The aperture of the instrument he suggests should be 8 inches, with circles of 3 feet diameter, read by four microscopes, and he thinks that a suitable position for it could be found about 90 feet north of the declination magnet, where "an unobstructed view could be secured by mounting it with its axis at a height of about 20 feet above the ground."

NOTES.

THE Ladies' *Soirée* of the Royal Society is being held this evening as NATURE goes to press.

THE annual meeting of the American Association for the Advancement of Science will be held at Rochester, N.Y., from August 18 to 24.

THE late Dr. W. J. Walker placed at the disposal of the Boston Society of Natural History a grand honorary prize "for such investigation or discovery as may seem to deserve it, provided such investigation or discovery shall have been made known or published in the United States at least one year previous to the time of award." This prize has been unanimously awarded to Prof. James D. Dana. In recognition of the value of Prof. Dana's scientific work, and in testimony of the Society's high appreciation of his services to science, the maximum sum of one thousand dollars has been awarded.

IN the new number of the Journal of the Marine Biological Association Mr. Ernest W. L. Holt gives an interesting account of the work he has lately done in connection with his North Sea investigations. The objects of these investigations, as explained in the report of Mr. Calderwood, the Director of the Plymouth Laboratory, are:—(1) to prepare a history of the North Sea trawling grounds, comparing the present condition with the condition say twenty or thirty years ago, when comparatively few boats were at work; (2) to continue, verify, and extend operations as to the average sizes at which the various food-fishes become sexually mature; (3) to collect statistics as to the sizes of all the fish captured in the vicinity of the Dogger Banks and the region lying to the eastward, so that the number of immature fish annually captured may be estimated; (4) to make experiments with beam trawl nets of various meshes, with a view to determine the relation, if any, between size of mesh and size of fish taken. It is obvious that a considerable time must elapse before trustworthy data can be collected on all these points by one inquirer. Mr. Calderwood therefore notes that in Mr. Holt's early reports it has been thought advisable not to treat each heading in detail, since one season of the year may be more suitable for collecting information on one point than on another, but rather simply to state the results of work accomplished. During the spawning season most attention must necessarily be given to heading No. 2, so that in Mr. Holt's present report the relation of size to immaturity is principally mentioned. Work of a similar nature done by Mr. Holt himself in Ireland, by Dr. Fulton in Scotland,

and by observers at Plymouth, shows that a very considerable variation takes place in the sizes at which fishes become sexually mature in different localities, and Mr. Calderwood thinks it is probably not too much to say that as surely as legislation will have to be resorted to for the preservation of fish until they have spawned, so surely will the matter have to be studied for each coast separately.

MR. CALDERWOOD records in his report that the demand on the Plymouth Laboratory for specimens to be used in laboratories and museums throughout the country increases, and requires constant attention. The Laboratory can supply specimens which, in very many cases, could not otherwise be obtained. The proper preservation of certain classes of soft animals is in itself an art developed during the last fifteen years, almost entirely by the persevering efforts of Signor Lo Bianco, of Naples. Within the past year these methods have been published, and it is hoped that with practice the specimens sent out from the Plymouth Laboratory may gradually gain the character so long possessed by the Naples specimens alone.

AT the general monthly meeting of the Royal Institution on Monday, June 13, the special thanks of the members were returned for the following donations:—Mrs. Bloomfield Moore, £80, Sir David Salomons, Bart., £50, Mr. Charles Hawksley, £50, for carrying on investigations on liquid oxygen.

A COMMITTEE appointed by the Botanical Club of Washington to consider the questions of a botanical congress and botanical nomenclature has lately presented its report, which the Club has unanimously adopted. While favouring the final settlement of disputed questions by means of an international congress, the committee do not regard the present as an opportune time. They recommend the reference of the question of plant nomenclature first to a representative body of American botanists, and suggest the consideration, by such a body, of various questions. Among these questions are the following: the law of priority, an initial date for genera, an initial date for species, the principle "once a synonym always a synonym," what constitutes publication?, the form of ordinal and tribal names, and the method of citing authorities.

THE anticyclone, which at the time of our last issue had lain over these islands for some days, then began gradually to give way, and in the night of the 9th northerly winds and cloudy weather set in over Scotland, while depressions formed over England, causing thunderstorms in this country and in Ireland, with heavy rainfall in places, as much as 1·1 inch being measured at Mullaghmore during the twenty-four hours ending 8h. a.m. on Saturday, the 11th. These changes in the distribution of pressure caused great fluctuations of temperature; the maxima observed over Scotland on the 10th were in some cases as much as 30° lower than those of the previous day, while in England, on the 11th and 12th, a still larger decrease of temperature was experienced. A small depression which lay over the south-east of England on Sunday, caused a steady rain for some hours in that part of the country; the maximum temperature registered in London was 51°, being about 18° below the average maximum for June. In fact, so low a maximum temperature has not occurred in London, in June, for at least a quarter of a century. On the night of the 19th the temperature on the grass fell to 29° at Oxford. During the early part of the present week an anticyclone, lying to the westward, extended over the western and northern parts of the country, and a large depression appeared to the southward of these islands, causing moderate northerly and north-easterly breezes, while temperatures continued low in all parts of the country.

THE Meteorological Council have just issued, as the completing portion of the *Weekly Weather Report* for 1891, tables giving improved monthly and annual means of temperature, rainfall, and bright sunshine for all the stations (65 in number) used in the preparation of that publication. The large amount of labour expended on the calculations, and the trustworthiness of the values may be judged of from the fact that the temperature means extend over 20 years, the rainfall over 25 years, and the sunshine over 10 years. A glance at the figures at any station is sufficient to show the chief characteristics of its climate, as compared with any other locality. They show that London has the highest mean maximum temperature in July, 72°·4; Cambridge, the lowest mean minimum, 31°·6 in December, although several other stations have a mean minimum of 31°·7 in that month, and Cambridge and Hillington have 31°·7 and 31°·8 respectively in January. The wettest station is Laudale, N.B., with an annual rainfall of 79°·57 inches, and the driest, Spurn Head, 20·92 inches. The stations with most and least sunshine are Jersey and Glasgow respectively, the deficiency of the latter being due to smoke.

DR. J. HANN laid before the Academy of Sciences at Vienna, on May 5, another of those elaborate investigations for which he is so well-known, entitled "Further Researches into the Daily Oscillations of the Barometer." The first section of the work deals with a thorough analysis of the barometric oscillations on mountain summits and in valleys, for different seasons, for which he has calculated the daily harmonic constituents, and given a full description of the phenomena, showing how the amplitude of the single daily oscillation first decreases with increasing altitude, and then increases again with a higher elevation. The epochs of the phases are reversed at about 6000 feet above sea-level as compared with those on the plains. The minimum on the summits occurs about 6h. a.m., and in the valleys between 3h. and 4h. p.m. The double daily oscillation shows, in relation to its amplitude on the summits, nearly the normal decrease, in proportion to the decreasing pressure, but the epochs of the phases exhibit a retardation on the summits, of as much as one or two hours. In the tropics, however, this retardation is very small. He then endeavours to show that these modifications of the daily barometric range on mountain summits are generally explained by the differences of temperature in the lower strata of air. In connection with this part of the subject, he considers that even the differences in the daily oscillations at Greenwich and Kew are mostly explained by the different altitude of the two stations, and by the fact that Greenwich is on an open hill. In the second section he has computed the harmonic constants for a large number of stations not contained in his former treatise of a similar nature, including some valuable observations supplied by the Brazilian Telegraph Administration, and others at various remote parts of the globe.

A SECOND attempt is to be made to build an Observatory at the top of Mont Blanc. As the workmen who tunnelled last year through the snow just below the summit did not come upon rock, M. Janssen has decided that the building shall be erected on the frozen snow. A wooden cabin was put up, as an experiment, at the end of last summer, and in January and early in the spring it was found that no movement had occurred. According to the Lucerne correspondent of the *Times*, the Observatory is to be a wooden building 8 metres long and 4 metres wide, and consisting of two floors, each with two rooms. The lower floor, which is to be embedded in the snow, will be placed a the disposition of climbers and guides, and the upper floor reserved for the purposes of the Observatory. The roof, which is to be almost flat, will be furnished with a balustrade, running round it, together with a cupola for observations. The whole building will rest upon six powerful screw-jacks, so that the equilibrium may be restored if there be any displacement of the snow foundations. The building is now being made in Paris, and will shortly be brought in sections to Chamounix. The transport of the building from Chamounix to the summit of

Mont Blanc and its erection there have been intrusted to the charge of two capable guides—Frederick Payot and Jules Bossonay.

LECTURES on subjects of great practical interest are being delivered daily in connection with the International Horticultural Exhibition. Mr. H. Cheshire will lecture to-day on "Guano: its origin and composition, use and abuse." Among the subjects of other lectures for which arrangements have been made are "The relation of insects to flowers," "Strawberry culture," and "The tomato: its diseases," by Prof. F. L. Cheshire; "Hatching: the management of the brooding hen," by Mr. W. Cook; and "Plant food and the formation of composts," by Mr. H. Cheshire.

DR. W. L. ABBOT has prepared for the Smithsonian Institution an excellent descriptive catalogue of the collection of ethnographical objects from Kilima-Njaro, presented by him to the National Museum. Dr. Abbot expresses his belief that Kilima-Njaro, with its cool, healthy, and bracing climate, will some day be a great sanatorium for Europeans from the hot and fever-stricken coast regions. He would be sorry, however, to see civilization invade this region, and hopes the day may be far distant when a railway shall open the way into the interior, and drive off "the herds of game that still pasture within sight of Africa's great snow mountains."

MESSRS. JOSEPH BAER AND CO., booksellers, Frankfort, are selling the botanical library of the late Prof. L. Just, director of the botanical garden connected with the Polytechnicum at Carlsruhe. The list includes many important works in various departments of botanical science.

MR. L. RYBOT writes to us from Southampton that he caught a very perfect specimen of the rare crimson speckled *Deiopeia pulchella*, on the afternoon of Friday last (June 10), in a field on the right bank of the Itchen, not far from Southampton.

IN 1874 the British Association published a volume of "Notes and Queries on Anthropology," the object being to promote accurate anthropological observation on the part of travellers, and to enable those who were not anthropologists themselves to supply information wanted for the scientific study of anthropology at home. A second edition has long been wanted, and a Committee was appointed by the British Association to consider and report on the best means for bringing the volume up to the requirements of the present time. The Committee recommended that the work should be transferred to the Anthropological Institute, and this proposal was accepted, the Association making grants amounting to £70 to aid in defraying the cost of publication. The new edition has now been issued, the editors being Dr. J. G. Garson and Mr. C. H. Read; and every one who may have occasion to use it will find it thorough and most suggestive. The first part—Anthropography—has been entirely recast; the second part—Ethnography—has been revised, and additional chapters have been written. Among the contributors to the volume are Mr. F. Galton, Mr. A. W. Franks, Dr. E. B. Tylor, General Pitt-Rivers, and many other well-known authorities.

MR. CYRUS THOMAS announces in *Science*, of May 27, that he has discovered the key which will unlock the mystery of the Maya codices, and, probably, the Central American inscriptions. The progress of decipherment will be slow, but he is confident that it will be ultimately accomplished. He has already determined the signification of some dozens of characters, and in several instances ascertained the general sense of a group forming a sentence, although there are a number of conventional symbols. Mr. Thomas holds that the great majority of the characters are truly phonetic, and that the writing is of a higher grade than has hitherto been supposed.

THE members of the Johns Hopkins Marine Station accumulated during the summer of 1891, in addition to the results of their special researches, many general observations upon the fauna of Jamaica. These notes are printed in the April number of the Johns Hopkins University Circulars, and will be of considerable service to any one who may desire to obtain what is called in the Circular "a preliminary view of the material."

THE new number of the *Internationales Archiv für Ethnographie*, contains interesting notes (in English) by A. Ernst, Caracas, on some stone-yokes from Mexico. R. Parkinson contributes (in German) a paper on tattooing among the natives of the district Siarr, on the east coast of New Mecklenburg, New Ireland. A paper on the development and geographical distribution of the various types of building in use among Finnish peoples is contributed by Axel O. Heikel, of Helsingfors. The illustrations, as usual, have been carefully prepared.

THE Society for Promoting Christian Knowledge has issued a fresh series of coloured representations of plants. They have been printed in Germany, and ought to be of good service to students and teachers of botany.

THE first volume of "A Treatise on Hygiene," edited by Dr. Thomas Stevenson and Mr. Shirley F. Murphy, will shortly be issued by Messrs. J. and A. Churchill. It consists of articles, by eminent writers, on many different phases of hygienic science. The second volume is in the press.

MR. C. F. MABERY gives in *Science*, of May 13, a full account of the new chemical laboratory of the Case School of Applied Science, Cleveland, Ohio. In devising plans for the laboratory, Mr. Mabery felt that while it was not good economy to construct a building several times larger than present needs demanded, it was important to provide for the possibility of unlimited extension. A plain, rectangular form was therefore designed, and it was found that extension of the main hall into a wing of any size would not interfere with a convenient arrangement of the rooms for present use.

ICEBERGS seem to be unusually plentiful in the Atlantic this year. According to a writer in the *Times*, the log of the Inman liner *City of Berlin*, which arrived on the 3rd inst., shows how dangerously close to the Transatlantic path the icebergs are hovering. On the afternoon of May 31, about 5.45 o'clock, the *City of Berlin* was in latitude 50° 20′, longitude 42° 15′. It was a clear and pleasant evening, and almost all the passengers were on deck. About 5 o'clock the air became very chilly, and the temperature of the water was very low. Captain Land at once suspected icebergs, and steered a more southerly course in the hope of avoiding them. About 6 o'clock, only a few miles to the north, a towering double-pinnacled berg was sighted. The berg was fully 200 feet high and about 600 feet long. Twenty minutes later another berg was sighted on a direct line with the first; between 6 and 8.30 o'clock four bergs were sighted. None of them was less than 100 feet high and 300 feet long; all were in a good state of preservation, and looked as though they would be able to drift about for some time. Icebergs have also been sighted by other vessels.

THE Todas, inhabiting the Nilgiri plateau, are not dying out gradually, as has long been supposed. The last census figures show that they have increased by no less than 10 per cent. during the last ten years, there being now nearly eight hundred of them altogether.

IN the new number of the Journal of the Straits Branch of the Royal Asiatic Society there is an interesting note on the little insectivore, *Tupaia javanensis*. It is very common in Singapore, and especially in the Botanic Gardens, where it may be often seen running about among the trees. It is easily mistaken for the common little squirrel (*Sciurus hippurus*), of which it has much the appearance. When alarmed it quickly darts up the trunk of the nearest tree, but it is a poor climber, and never seems to go high up like the squirrel. Besides these points of resemblance, it appears to be largely frugivorous. It was found that the seeds sown in boxes were constantly being dug up and devoured by some animal, and traps baited with pieces of coco-nut or banana were set, and a number of tupaias were caught. These being put into a cage appear to live very comfortably upon bananas, pine-apple, rice, and other such things; refusing meat. The Rev. T. G. Wood, in his "Natural History," states that *T. ferruginea* is said to feed on beetles, but to vary its diet with certain fruits. The common species at Singapore seems to be almost entirely frugivorous, though its teeth are those of a typical insectivore.

THE thirtieth Bulletin of the Botanical Department, Jamaica, contains a careful paper, which ought be be very useful, on the sugar-cane borer, by which much damage is being done in sugar plantations. The author is Mr. T. D. A. Cockerell, Curator of the Institute of Jamaica. Another contributor to the Bulletin, writing of gardening in Jamaica, mentions that about a year ago Messrs. Cannel and Sons, Swanly, Kent, sent her some small plants of chrysanthemums by post. They were all new and valuable; and the English season being so short, Messrs. Cannel and Sons begged her to try whether she could succeed in getting seed from these for them, offering to send her a collection of choice chrysanthemums in repayment of her trouble should she be successful. Out of the six plants one died, killed by a grub; the rest turned out magnificent, blowing with a profusion such as she had seldom seen before—they were perfect umbrellas of bloom; but the flowers died off without seeding. The plants then threw out a perfect little forest of offsets, and she finds that any cuttings broken off from the old plants will root easily.

A METHOD of rabbit-destruction which has been tried with considerable success in the Hay district, is recommended by the *Agricultural Gazette of New South Wales* as worthy of the consideration of pastoralists throughout the colony, more especially where the rainfall is light. The destroying agent is poisoned water, which is prepared as follows:—Cover 1 ounce of strychnine with concentrated hydrochloric acid, or what is commonly known as strong muriatic acid or spirits of salts, and leave to soak all night. The mixture easily dissolves in half a gallon of boiling water. After making the solution, bottle off and use as required. A pint of the mixture will poison 60 gallons of cold water; possibly a weaker mixture might be efficacious. This system has been adopted at Benerembah Station, sixteen shallow 8- to 10-gallon troughs being used to each tank, and the number of rabbits poisoned at each tank nightly is stated to be 10,000. In the Mossgiel district no less than 27,000 rabbits were destroyed in two weeks by the use of poisoned water.

THE idea of flower-farming for perfumes seems to be exciting a good deal of interest in New South Wales, as many inquiries on the subject have lately been submitted to the Agricultural Department. There are at present in the colony no means of illustrating the practical operations of this industry, but the *Agricultural Gazette of New South Wales* hopes that this deficiency will soon be supplied by the institution of experimental plots on one or more of the experimental farms. The *Gazette* points out that in scent farms large quantities of waste material from nurseries, gardens, orchards, and ordinary farms might be profitably utilized, while occupation would be found for some who are unfit for hard manual labour. A Government perfume farm was lately established at Dunolly, in Victoria, and this promises to be remarkably successful.

AT the meeting of the Field Naturalists' Club of Victoria on March 14, Prof. Baldwin Spencer, the President, gave an interesting account of a trip he had made to Queensland in search of Ceratodus. Special interest attaches to this form, since it is the Australian representative of a small group of animals (the Dipnoi) which is intermediate between the fishes and the amphibia. Ceratodus has its home in the Mary and Burnett Rivers in Queensland, whilst its ally, Lepidosiren, is found in the Amazon, and another relative, Protopterus, flourishes in the waters of tropical Africa. Although unsuccessful in obtaining the eggs of Ceratodus, owing to the early season, Prof. Spencer was able, from a careful study of the surroundings under which the animal lives, to infer that its lung is of as great a service to it during the wet as during the dry season—a theory in direct opposition to the generally accepted one that the lung functions principally during the dry season, when the animal is inhabiting a mud-cocoon within the dry bed of the river.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Oswald Norman; a Common Fox (*Canis vulpes*), British, presented by Mrs. Onslow Wakeford; two Four-horned Antelopes (*Tetraceros quadricornis* ♀ ♀) from India, presented by Mr. W. F. Sinclair; a Magellanic Goose (*Bernicla magellanica*) from the Falkland Islands, presented by the Rev. J. Chaloner; six Common Lizards (*Lacerta vivipara*), a Slowworm (*Anguis fragilis*), British, presented by Mr. Percy W. Farmborough; three Little Green-winged Doves (*Chalcophaps chrysochlora*) from North Queensland, deposited; two Diamond Snakes (*Morelia spilotes*), a Punctulated Tree Snake (*Dendrophis punctulatus*), a Bearded Lizard (*Amphibolurus barbatus*), a Burton's Lizard (*Lialis burtoni*) from Australia, received in exchange; a Great Kangaroo (*Macropus giganteus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE LATE NEW STAR IN AURIGA.—A very interesting table, showing a summary of all the observations made with regard to the magnitude of the late new star in Auriga, will be found in *L'Astronomie* for June. Commencing with the photographs taken by Prof. Pickering, when the Nova was very nearly of the 12th magnitude, the table shows a tremendous increase of brilliancy up to December 18, when it had reached a maximum, its magnitude then being about 4·5. From that date to March 2, the diminution in intensity was only very slight, being reduced only by about one magnitude, but, subsequent to this, the fading was nearly as rapid as the brightening, the star diminishing, on an average, a magnitude in a period of about 3·2 days.

PHOTOGRAPHIC MEASURES OF THE PLEIADES.—The third number of the "Contributions from the Observatory of Columbia College, New York," consists of the Rutherfurd photographic measures of the group of the Pleiades reduced by Mr. Harold Jacoby. These photographs were among the complete set of original negatives that were presented to this Observatory by Mr. Rutherfurd, and were taken in the years 1872 and 1874. This special group was chosen for reduction in order to investigate the accuracy obtainable by the methods employed, and the results show that the reduced places can be thoroughly relied upon. The table containing a catalogue of the stars in question gives the places for the epoch 1873·0, together with the precessional and secular variation. In the discussion of the results, the Yale and Königsberg heliometer measures have been used for the sake of comparison, and Mr. Jacoby clearly demonstrates that the photographic results are of very considerable accuracy. Taking the case of the right ascensions, the difference of the residuals, obtained from the Yale and New York results, and those from Yale and Königsberg, amounts in only two cases to as much as 0″·50, while the mean may be roughly estimated as less than 0″·25. That part of the table relating to the declinations furnishes equally satisfactory values, showing us that, for any future study regarding the determination of proper motions in this region, these photographic observations ought to be taken into account. The average probable errors in right ascension and declination amount to ± 0″·06 and ± 0″·05 respectively; the actual probable errors somewhat exceeding these values, as they involve the scale inaccuracies and other possible sources of error.

The Planet Mars.—In the early morning Mars is now visible on our eastern horizon. This period of 1892 will be the most favourable for observation that we have had since the year 1877. The opposition takes place on August 4 next, when the planet is near perihelion, so that its proximity to us will not be quite so great as was the case in 1877. The longitude of the planet at the time of its perihelion passage will be 333° 49′, but our earth will not reach this until August 27. The apparent diameter on the 18th of this month will amount to 17″·66, while on August 5 it will be 24″·78; the phases for these two dates will be respectively 1″·34 and 0″·05. The positions for the 17th, 21st, and 25th of this month are as ollows:—

June	R. A.	Decl.
17	21h. 16m.	−20° 4′
21	21h. 20m.	20° 7′
25	21h. 22m.	20° 13′

L'Astronomie for June contains a very interesting article by M. Camille Flammarion, in which some quite recent observations of this planet are inserted. There are also several illustrations of the physical features, including the new map by M. Lohse and the drawings made by M. Nieston during the year 1888.

GEOGRAPHICAL NOTES.

The French Ministry of Public Instruction has authorized M. Ch. Almand, of the Natural History Museum of Limoges, to study the Seychelles Islands in detail with special reference to their fauna.

The Geographical Society of Lima has just issued the last number of the first volume of its *Boletin*, a most creditable publication containing many articles bearing on the geography of Peru and the Andes. Amongst the more important papers in the current issue are a monograph on Lake Titicaca, a discussion of the climatology of Peru, by Dr. Luis Carranza, and the report of a recent Commission sent out by the Peruvian Government to inspect the new road across the Andes leading to the highest navigable point on the eastern rivers. The road starting from Chicla, the temporary terminus of the Oroya railway, crosses the watershed at Casapalca at 17,500 feet of elevation, passes Tarma, Palca, La Merced, and thence runs northward through a little-known region inhabited by native tribes to Puerto Tucker, at the junction of the Pichis with the navigable tributaries of the Ucayali. In referring to this road at a recent meeting of the Royal Geographical Society, the Peruvian Consul pointed out that it would be easy, if a railway were constructed following the line of this road, and connecting steamers run on the Amazon and Ucayali, to reach Lima from London in twenty days instead of a month as is now necessary. Other papers in the *Boletin* deal with the archæology of the Andes region; all branches of geography being well represented.

A new Russian Expedition to Eastern Tibet and Sze-chuan in China has been decided on, and will set out next year, under the leadership of M. Potanin. It is intended to spend three years in the exploration, a sum of 30,000 rubles (about £3000) being granted by the Russian Government towards the expenses. Capt. Roboroffski accompanies the expedition, on the staff of which various scientific specialists will also be placed.

At the May meeting of the Paris Société de Géographie the great gold medal was presented to M. Élisée Reclus for his "Nouvelle Géographie Universelle," a work which, though unfinished, is of unique value, and is respected and consulted in all countries. This award is significant of the feeling that careful and conscientious collation and generalization of the work of explorers and travellers occupies a much higher place in the science of geography than has been hitherto accorded it. Amongst those to whom other gold medals were awarded are the Prince of Monaco, for oceanographical research; M. A. Paine, for explorations in Indo-China; M. J. de Morgan, for travels in Persia and Kurdistan; M. H. Coudreau, for ten years of exploration in the interior of French Guiana; and M. Alfred Fourneau, for exploration in French Congo.

NAPLES ACADEMY OF SCIENCES.[1]

This volume has been much delayed on account of a memoir by Prof. Trinchese on *Rhodope veranii*. That paper should have constituted the first of the present volume, but a notice leaf after the title-page informs us that it will be sent later on as a separate pamphlet. In consequence the volume starts with an elaborate paper in French, of 72 pages and three plates, by M. S. Kantor, "Sur la solution canonique du problème des transformations birationnelles périodiques," iv.^{e} partie. This memoir treats of "Méthodes et problèmes; les caractéristiques internes et les caractéristiques permutables; les caractéristiques à 6, 7, 8 points; théorie arithmétique des caractéristiques de transformations birationnelles; les complex anallagmatiques de singularités et de la réductibilité des caractéristiques par équivalence birationnelles; les groupes impropres; les matrices birationnelles de M. de Jonquière; et sur plusieurs groupes de caractéristiques et de transformations."

Prof. F. Bassani contributes a paper on the Miocene Ichthyolites of Sardinia, from specimens collected and placed in his hands by Prof. Lovisato. The tables, cross references, and index are admirable, and of great use to specialists in this branch. Many of our English workers, and above all, Societies, should take a lesson from this. It is occasionally the author of a paper, but far more frequently the responsible authorities of some scientific body, that are the cause of such valuable details not appearing in a paper. How often does it occur that for a paltry economy, a valuable memoir is cast upon the world a dismembered trunk, little comprehensible to the reader, and often a curse to the writer, who is exposed to all sorts of absurd criticisms because his original statements have been pruned to deformed stumps and his tables entirely suppressed.

Several old species are more fully illustrated by descriptions and neat plates drawn by Mrs. Bassani, as well as a new species of Thyrsites, Thynnus, Lamna, Myliobatis, &c.

Prof. Eugenio Scacchi has a memoir on the crystallography of certain new salts obtained by Prof. F. Mauro. The fluoximolybdate of copper is found to be monoclinic. Hypofluoximolybdate of copper is also monoclinic, whilst the hypofluoximolybdate of zinc is rhombohedral. Observations were difficult on account of the great deliquescence of these salts. The memoir is accompanied by one plate of crystal drawings.

Dr. Otto Schmiedeknecht, on his return from an entomological excursion to the Ionian Islands, placed in the hands of Prof. A. Costa all the Tenthredinidæ and Cephina that he had collected there. Prof. Costa describes these under 68 species, 9 of which are new. This is followed by a new genus of Italian Tenthredinidæ, named Laurentia, represented by the species *Laurentia Craverii*. The third section of this "Miscellanea Entomologica" is constituted by the description of four species of Armenian Hymenoptera: *Hylotoma cyanura*, *Allantus violaceipennis*, *Lissonota ducalis*, and *Lissonota decorata*. The "Miscellanea Entomologica" terminates with a new African Blattid, the *Derocalymma Brunneriana*, and is illustrated by one plate of figures in black.

Prof. G. Nicolucci, in a "Glimpse at the Ethnology of Egypt," discusses the different theories concerning the origin of the ancient Egyptians. By comparing the results obtained from historical records, monuments, anatomical observations, and descriptions of the people by ancient writers, he concludes (1) that the Egyptians belong to a white family related in prehistoric times to a Semitic branch; (2) that their physical characters form a type apart, which is clearly revealed in the monuments and the skulls obtained from the tombs of all periods; (3) that this type is the purer the more remote is the period of the monuments; (4) that it is true the immigration of other people into Egypt modified in part the primitive type of the population, but that the principal part of the Egyptians have always retained their primitive characters; (5) at the present, although the type has been crossed by intermarriage with different people in the cities, and other points frequented by strangers, it retains its original character in the Fellah, who are the true and legitimate modern descendants of the constructors of the Pyramids.

Prof. Nicolucci considers the Copts to be descended from ancient Egyptians, but with some infiltration of negro blood. The paper is accompanied by two plates, one of several modern Egyptian types, and one of the portrait of Rameses II. side by side with that of a Fellah.

---

[1] *Atti della Reale Accademia delle Scienze Fisiche e Matematiche di Napoli*, Serie Seconda, vol. iv., Napoli, 1891.

Signor G. F. Mazzarelli contributes some researches on the morphology and physiology of the glands of Bohadsch in the Aplysiidæ (the opaline gland of Vayssière). He also gives the diagnosis of a new species of Aplysia. The author gives an elaborate histological description of the organ illustrated by two coloured plates, and amongst other conclusions shows that three liquids are secreted—a white odoriferous, a violet, and a mucous—which he declares to have an important biological value, and to concur with the secretions of the mantle for the defence of the animal.

Dr. N. Terracciano in a note on some plants of the flora of Terra de Lavoro describes several species so far not met with in that district, others not included in the Italian flora, and some new species and varieties. Figures are given of *Arabis surculosa*, *Amaranthus crispus*, and *Kœleria collina*.

Next follows a monograph of the fossil Pristis, with a description of a new species (*Pristis lyceensis*) from the Miocene limestone of Lecce, and of course figured.

Dr. L. Manfredi has an interesting paper on the contamination of the street surface of large cities, from a hygienic and sanitary engineer's point of view, with special reference to Naples. Sweepings of the streets were made at 9 a.m.—that is, after the regular cleansing had been performed, so that the materials collected represented what remains all the day to contaminate the air and whatever objects it comes in contact with. The materials, collected with all due precautions, were submitted to bacteriological and chemical analysis. One gramme of fresh sweepings contains from 910·000 to 668,000,000 vital or living bacteria, or double the amount found in fresh fœces, or about 1319 times richer than drain water. Compared with the streets of Munich we find that the author there found 8000 to 12,840,000. He demonstrates that, so far as Naples goes, the more cleanly kept are the streets the lower is the number of bacteria in their sweepings, whilst they or their spores have great resisting powers to heat, sunlight, and desiccation. They are most abundant in the temperate seasons of spring and autumn; small rains increase them, torrents markedly diminish them. The Schizomycetes are the predominant type, but ferments and moulds are common. The chemical examination is equally interesting, and, as the author shows, the material is a most favourable culture medium for micro-organisms; which research leads up to a series of experiments to show how the number of these increase up to a certain date and then diminish in a given sample of sweepings; the effects of rain in facilitating this growth are demonstrated, and also the gases given off as the result of such changes.

The inoculation experiments are also not without interest. An examination of the sub-soil on the same lines is of great importance, and several practical and important conclusions are drawn from these researches, which the limits of space forbid our more fully reviewing. The memoir is one that should be consulted by every municipal officer.

Signor G. F. Mazzarelli has another long paper on the morphology and physiology of his favourite Aplysiæ of the Gulf of Naples, and illustrated by four plates.

Altogether this volume does credit to the Academy, but one regrets not to see papers by some more of its members.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In a Convocation held on June 7, the thanks of the University were ordered to be conveyed to Mr. C. D. E. Fortnum, Hon. D.C.L., for his munificent gift to the Ashmolean Museum, and an indenture was sealed, the provisions of which place the Ashmolean Museum on an entirely new footing.

In the year 1888 Dr. Fortnum gave to the University a large portion of his collection of antiquities and works of art, which had been exhibited on loan in the upper room of the Ashmolean Museum. Dr. Fortnum has now notified his intention of bequeathing to the University the remainder of his collection together with his library, and he has undertaken to transfer to the University a sum of £10,000 on certain conditions, the main object of which is to provide for the care and maintenance of the Museum in the future. Under the indenture, which was signed on Tuesday last, the University is bound—

(1) To provide a sum, not exceeding £11,000, for the erection of a new Ashmolean Museum, on ground adjoining the University Galleries.

(2) To provide a sum, not exceeding £4000, for the fitting up and furnishing the Museum.

(3) To augment to £600 a year, at least, the income arising from Dr. Fortnum's benefaction of £10,000.

Dr. Fortnum's kindly intentions to the new Ashmolean Museum include a further bequest to the University of £5000 contingent upon the University voting the £15,000 for buildings, fitting, and furniture. With regard to this amount the University authorities make the following remark:—"Of the £11,000 required for the building, it appears that the Curators of the University Chest will have funds in hand in the course of this year and next, out of which this expenditure may be defrayed. It is right, however, to state that this will leave the University Chest for the present without further resources, in the form either of stock or of cash, for meeting any other new expenditure upon a large scale."

It is proposed that the old Ashmolean Museum, when no longer required for its present purpose, shall be available as an extension for the Bodleian Library, for which additional accommodation must have soon been provided.

The University Observatory.—The annual meeting of the Board of Visitors took place on Wednesday, June 8, when the Savilian Professor (Rev. C. Pritchard, D.D., F.R.S.) read his annual report. After remarking on the present condition of the buildings and instruments, the Professor said:—

"As anticipated in the last report, the work connected with stellar parallax is now complete, and I have placed upon the table a manuscript containing the result of that research. I need hardly say that it has been a work of unremitting labour, and one which has occupied the strenuous efforts of myself and the Observatory staff during the last four years. The manuscript thus completed consists of (1) the concise but complete history of all effective researches in stellar parallax up to the present date; (2) the results of the parallax work completed in this Observatory, extending on the whole to some thirty stars; (3) a catalogue of all parallactic determinations effected by other astronomers.

"The provision of photometric catalogues of stars of the ninth and eleventh magnitudes, within small specified areas for the use of the eighteen Observatories engaged on the international chart of the heavens, has been effected, and the results distributed through the agency of the Paris Observatory. The cause of this proceeding originated in the unsuccessful attempts to secure the required uniformity of stellar magnitude on the photographic plates by the employment of metallic gauze screens of one definite mesh. Much time was consumed on the experimental research into the action of such screens on the photographic image, and in the course of the inquiry certain unexpected and interesting results came to light, the substance of which I communicated to the Paris Academy, and which were subsequently published in the Transactions of that body. It is satisfactory to find that these photometric determinations have been appreciated and found to be of practical service, and have been acknowledged as such by both the Directors of the Greenwich and Paris Observatories.

"Notwithstanding these very serious interruptions, considerable progress has been made in securing the photographic plates for the international chart and catalogue. In number these plates amount to about 150, and it is hoped in future they will accumulate more rapidly, since the work on the preparation of these aforementioned photometric catalogues is now complete."

The report concludes with the usual acknowledgments to the assistants, and with this very satisfactory expression, on which we beg to congratulate the Savilian Professor—"The state of my health and other circumstances prevented my being present at the last meeting of the Board, but I am glad to say that the anticipation of the speedy and complete recovery, mentioned in the last report, has been fully realized."

Radcliffe Travelling Fellowship.—The Examiners for this Fellowship give notice that a Fellowship is thrown open this year to all persons who have been placed in the First Class in the School of Natural Science, without further restriction. The examination will be as far as possible in the subjects specified by the candidates who offer themselves for examination, and will take place in the first week in November.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 19.—"On the Measurement of the Magnetic Properties of Iron." By Thomas Gray, B.Sc., F.R.S.E. Communicated by Lord Kelvin, P.R.S.

This paper gives the method of experiment and results obtained in some investigations on the time-rate of rise of current in a circuit having large electromagnetic inertia. The experiments were made on a circuit containing the coils of a large electromagnet having laminated cores and pole pieces. The mean length of the iron circuit was about 250 cm., and its cross section 320 sq. cm. The magnetizing coil had 3840 turns, when all joined in series, and a resistance of 10·4 ohms. The coils were so arranged that they could be joined in a variety of ways so as to vary the resistance, inductive coefficient, &c., and also to allow the magnet to be used either as an open or a closed circuit transformer.

The electromotive force used in the experiments was obtained from a storage battery, and the method of experiment was to trace the curve, giving the relation of current to time, on a cronograph sheet.

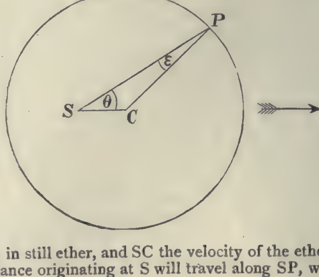
One set of experiments shows the effect of varying the impressed E.M.F. on the time required for the current to attain any given percentage of its maximum strength. The results show that for any particular percentage there is always a particular E.M.F. which takes maximum time. Thus for the circuit under consideration, and with successive repetitions of the current in the same direction, it takes longer time for the current produced by an impressed E.M.F. of 4 volts to reach 95 per cent. of its maximum than it takes for the current produced by either 3 or 5 volts to reach 95 per cent. of their maximum. The results show also that, within considerable limits, the time required for the current to become uniform is on the whole nearly inversely proportional to the impressed E.M.F., and that for moderate values of the E.M.F. the time may be very great; when the E.M.F. was 2 volts, and the current sent in such a direction as to reverse the magnetism left in the magnet by a previous current of the same strength, the time required for the current to establish itself was over three minutes. The difference of time required for repetition and for reversal of previous magnetization was also very marked when the iron circuit was closed. The results show that great errors may arise by the use of ballistic methods of experiment, especially when weak currents are used, and that for testing resistances of circuits containing electromagnets, a saving of time may be obtained by using a battery of considerable E.M.F.

Another set of experiments gives the effect of successive reversals of the impressed E.M.F. at sufficient intervals apart to allow the magnetization to be established in each direction before reversal began. In this set also the effect of cutting out the battery and leaving the magnet circuit closed is illustrated, showing that several minutes may be required for the magnet to lose its magnetism by dissipation of energy in the magnetizing coil. The effect on these cycles of leaving an air space in the iron circuit is also illustrated. It is shown that a comparatively small air space nearly eliminates the residual magnetism, and diminishes considerably the rate of variation of the coefficient of induction and the dissipation of energy in the magnet.

Several cycles are shown for the magnet used as a transformer with different loads on the secondary. The results give evidence that there is less energy dissipated in the iron the greater the load on the secondary of the transformer.

Some experiments are also quoted which go to show that the dissipation of energy due to magnetic retentiveness (magnetic hysteresis) is simply proportional to the total induction produced when the measurements are made by kinetic methods. Reference is made to the recent experiments of Alexander Siemens and others which seem to confirm this view.

Physical Society, May 27.—Mr. Walter Baily, Vice-President, in the chair.—The following communication was read:—On the present state of our knowledge of the connection between ether and matter: an historical summary, by Prof. O. J. Lodge, F.R.S. Referring to difficulties connected with the aberration of light, if the medium were supposed to be carried along by the earth in its orbit, Dr. Lodge described Boscovich's suggested experiment with a telescope filled with water, carried out by Klinkerfues, who was led to conclude that the aberration constant depended on the medium within the telescope. Klinkerfues's experiments were repeated by Sir G. B. Airy, but not confirmed. Astronomical observations were not necessary to determine the point at issue, for a fixed source near a collimator might be used with advantage. Hoek had examined the subject in this way with similar negative results. It might therefore be concluded that surveying operations are unaffected by terrestrial motion. This result, however, did not prove the existence or non-existence of an ether drift relative to the earth, for, since the source and receiver move together, any effect produced by such a drift would be compensated by aberration due to motion of the receiver. Speaking of refraction, he pointed out that, if the ether were stationary in space, glass and other terrestrial bodies would have ether streaming through them, and that the refraction of, say, glass might differ as the direction of the ether drift through it varied. To test this, Arago placed an achromatic prism over the object-glass of a telescope on a mural circle, and observed the altitude of stars. To vary the direction of the ether drift through the prisms, stars in different azimuths were observed; but the results showed no appreciable change in the deviation produced by the prism due to direction of the earth's motion. Maxwell used a spectroscope to test the same point. Light from illuminated cross wires passed through the telescope, prisms and collimator, and was reflected back along the same path by a mirror and viewed through the telescope. Observations made with different aspects of instrument showed no change in the relative positions of the wires and their images. Mascart had also tried the experiment with simpler apparatus, but was unable to detect any change. These observations naturally suggest that the ether is at rest relative to the earth, but the apparently simple nature of aberration makes this view difficult to hold. Both phenomena are consistent with Fresnel's hypothesis that only the excess of ether, which the substance possesses over that of surrounding space, moves with the body, for on this supposition the effects of altered refraction and ether drift compensate each other. Fresnel's view is practically established by Fizeau's well-known experiment on the effect of moving water on the velocity of light, and by the more accurate numerical results obtained by Michelson. The only other theory which accounts for the experimental results is one by Prof. J. J. Thomson, which requires that the velocity of light in Fizeau's experiment should be altered by half the velocity of the medium. For media whose refractive indices are $\sqrt{2}$, the two theories lead to the same result, and as the indices of substances such as water do not differ much from this value, it is difficult to discriminate between them. Looked at in another way, Fizeau's experiment raises a difficulty, for, as Dr. Lodge pointed out, all water is moving with the earth, hence light should be hurried or hindered according to the direction in which it passes through the water. This effect doubtless exists, but the results of it have never been detected by experiment. It is therefore necessary to inquire why the effect could not be observed directly, for the experiment had been tried with interference apparatus by Babinet, Hoek, Jamin, and Mascart, and in no case was any effect observed. It would therefore seem as if the ether must be stagnant, *i.e.* stationary relative to the earth. Mascart had also tested whether Newton's rings, or the rotary power of quartz, were affected by ether drift, but with negative results. These observations are, however, likewise compatible with Fresnel's hypothesis of an ether fixed relative to matter, and a free ether of space permeating all substances, for, according to this view, there is no more motion of the ether in water or glass than in air; hence the time of journey round a closed contour is independent of the direction in which the light traverses that contour. The time of journey between two points is also unaffected by terrestrial motion, as was proved by the experiments of Babinet, Hoek, and Mascart on interference; hence he (Dr. Lodge) inferred that ether was either stagnant or had a velocity potential. In moving ether it was necessary to define a ray, and Lorentz's method is the best. Suppose CP represents the velocity of light (V) in still ether, and SC the velocity of the ether (v), then a disturbance originating at S will travel along SP, which is the



direction of the ray, whilst CP is the wave normal. In the above figure,

$$\frac{\sin \epsilon}{\sin \theta} = \frac{\mathrm{SC}}{\mathrm{CP}} = \frac{v}{\mathrm{V}} = \alpha, \text{ the constant of aberration.}$$

The velocity along the path of the ray is SP. Calling this velocity V′, we have

$$\mathrm{V}' = \mathrm{V} \cos \epsilon + v \cos \theta.$$

The path of a ray is determined by the time of journey being a minimum, and the formula

$$\mathrm{T} = \int_{\mathrm{A}}^{\mathrm{B}} \frac{ds}{\mathrm{V}} = \text{a minimum},$$

is the equation to a ray, where A and B are the extremities, and *ds* an element of the path. If the ether be moving, V′ must be substituted for V, and we get—

$$\mathrm{T}' = \int_{\mathrm{A}}^{\mathrm{B}} \frac{ds}{\mathrm{V} \cos \epsilon + v \cos \theta} = \text{a minimum}.$$

This integral can be written exactly—

$$\mathrm{T}' = \int \frac{ds}{\mathrm{V}} \frac{\cos \theta}{1 - \alpha^2} - \int \frac{v \cos \theta}{\mathrm{V}^2(1 - \alpha^2)} ds$$
$$= \frac{\mathrm{T} \cos \theta}{1 - \alpha^2} - \int \frac{v}{\mathrm{V}^2} \cdot \frac{\cos \theta}{1 - \alpha^2} \cdot ds.$$

The last term is the only one involving the first power of ether drift, and it vanishes in case there is a velocity potential; for, since $v \cos \theta = \frac{d\phi}{ds}$, where ϕ is the velocity potential, it may be written $\frac{\phi_{\mathrm{B}} - \phi_{\mathrm{A}}}{\mathrm{V}^2(1 - \alpha^2)}$; and so its value depends only on the end points and not on the path. If these points are the same, *i.e.* the contour is closed, it becomes zero, and reconciles all the experiments hitherto made. It must be admitted, however, that if α is not a constant, the question is again opened, but there is no reason to suppose it can vary in the same horizontal plane. If the medium be changed, V becomes $\frac{\mathrm{V}}{\mu}$, and, in order to retain the same velocity potential in the changed medium, v must become $\frac{v}{\mu^2}$, which is Fresnel's law. Hence Prof. Lodge pointed out that the velocity potential condition includes Fresnel's law as a special case. It can, in general, be inferred that *no first order optical effect due to terrestrial motion can exist in a detectable form.* It is always compensated by something else. Quantities of the second order of magnitude must, therefore, be attended to. From the first equation above, it follows that

$$\cos \epsilon = \sqrt{1 - \alpha^2 \sin^2 \theta},$$

and the time of journey in moving ether is given by

$$\mathrm{T}' = \mathrm{T} \frac{\sqrt{1 - \alpha^2 \sin^2 \theta}}{1 - \alpha^2},$$

where T is the time if everything were stationary. This is, in brief, the theory of Michelson's recent experiment. If the light travels along the ether drift, $\theta = 0$ and $\mathrm{T}_1 = \frac{\mathrm{T}}{1 - \alpha^2}$; whilst if $\theta = 90°$, $\mathrm{T}' = \frac{\mathrm{T}}{\sqrt{1 - \alpha^2}}$. Therefore the velocity along the ether drift should differ from that across the drift in the ratio of $\sqrt{1 - \alpha^2} : 1$. This point has been very carefully tested by Michelson, but nothing approaching to a quarter of the theoretical effect was observed. His negative result would seem to preclude any relative motion, even irrotational, and shows that the ether is at rest relative to the earth's surface. On the other hand, the author (Dr. Lodge) had recently made experiments on the influence of rapidly-rotating steel disks on the ether, which prove that the ether is not affected by the motion of contiguous matter to the extent of 1/200 part of the velocity of the matter. Thus, these two experiments are at present in conflict. Prof. Fitzgerald has suggested a way out of the difficulty by supposing the size of bodies to be a function of their velocity through the ether. Returning to the statements which have been made of Fresnel's law, Glazebrook has shown that actual extra-density of ether is not necessary, for, if the virtual mass be altered, the same results follow; all that is required is a term depending on the relative acceleration of ether and matter. To modern ideas the loading of the ether by the presence of matter is most likely to be correct, and the observed effects of relative motion are regarded as the results of secondary reactions of matter on ether. On this view, the ether of space may be wholly unaffected by the motion of matter. On the vortex ring theory of matter, it is not unnatural to suppose that the ether in its neighbourhood should be only affected irrotationally by its motion. And if the velocity potential be granted, nothing of the nature of viscosity being admissible, the results of all the interference, refraction, and aberration experiments could be predicted, and the whole theory is as simple as it can possibly be. The only trustworthy experiment ever made which tends against this view is that of Michelson. The author surmised that this must somehow be explained away. In reply to a question from Prof. Ayrton, Dr. Lodge said that when air was substituted for water in Fizeau's experiment no effect was observed. This might have been expected, for the difference in the times of journey by the two paths depended on $\frac{\mu^2 - 1}{\mu^2}$, and as μ is nearly unity for air, the air effect is too small to see. [In Hoek's interference experiment it might be said that the effect of ether moving in stationary water is balanced by that of the ether moving in stationary air; but while motion of water itself would disturb the balance, motion of air would do nothing appreciable. The only kind of motion that could display an optical effect is rotational motion, or motion of layers at different speeds, not a simple uniform drift. Prof. J. V. Jones asked how the Fizeau experiment could be expressed on the loaded ether theory; for, since the speed of matter affects the velocity of light, it seemed to involve a directional loading. A mere extra-density term, or acceleration coefficient, will not explain this; it seems to require a coefficient of a velocity term. This question has been hinted at by Lord Rayleigh, who points out (under the heading "Aberration," NATURE, xlv. p. 499) that the rate of propagation of waves on a loaded string will be affected by a travelling of its load. The question is not perfectly simple, and the analogy not complete. A good deal depends on the nature of the connection symbolized as "loading."[1]]

Royal Microscopical Society, May 18.—Dr. R. Braithwaite, President, in the chair.—Mr. R. T. Lewis, in his paper on the process of oviposition as observed in a species of cattle tick, said that the tick was observed under a low power; after some time the head with the extended rostrum and palpi was retracted, producing a deep depression, the softer adjacent portions of the ventral surface between the basal joints of the first pair of legs being drawn over the margin. Parts surrounding the depression changed colour, and a white vesicle appeared upon the lower internal wall. The palpi separated, so that they rested on each side of the vesicle. A membranous body, glistening with mucus, was protruded from the cavity, from the lateral extremities of which two papillæ were thrown out, extending across the depression. The vesicle was then elongated and embraced by the papillæ; through its walls an egg was seen in motion, which, being delivered into the grasp of the papillæ, the ovipositor at once retracted. The papillæ closed round the egg, covering it with an albuminous secretion, and withdrew, leaving it suspended from the under surface of the dorsal plate. The palpi closed together until in contact with the rostrum, the head elevating, clearing the egg out of the depression, leaving it adhering to the outer margin: the entire process of laying each egg occupying a period of 2 min. 42 sec. Mr. A. D. Michael remarked that the word "head" was somewhat misleading, because these animals had no heads in the sense in which the term applied to insects, but the whole movable organ was really the rostrum.—Mr. E. M. Nelson read a note on penetration in the microscope, showing that for his own sight the penetrating power was only one-seventh of that given by Prof. Abbe, whose myopic sight accounted for the difference in the estimate.—Mr. Nelson also read a note on rings and brushes of crystals, for the observing of which a petrological microscope was generally thought to be necessary. This was not essential, as it was really a telescopic object. All that had to be done was to convert the microscope into a telescope by placing an objective inside the tube of the instrument.

Geological Society, May 25.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—On *Delphinognathus conocephalus* (Seeley) from the Middle Karoo Beds, Cape Colony, preserved in the South African Museum, Cape Town, by Prof. H. G. Seeley, F.R.S. The skull described in this paper is believed by Mr. T. Bain to have been collected by himself near Beaufort West. The preservation of the specimen leaves something to be desired, but notwithstanding defects the skull belongs to a most interesting Anomodont, indicating a new family of fossil Reptilia. The skull is fully described in the paper, and its relationships are discussed. The author has already given reasons for regarding *Ælurosaurus felinus*, *Lycosaurus curvimola*, and their allies, as referable to a suborder *Gennetotheria*, which is nearly related apparently to the *Pelycosauria*, and lies midway between the typical *Theriodontia* and the *Dicynodontia*. It is to this suborder that *Delphinognathus* may be referred, though it forms a family-type distinct from the *Ælurosauridæ*, distinguished by the conical parietal with a large foramen, the anterior supracondylar notch in the squamosal bone, and other modifications of the skull and teeth.—On further evidence of *Endothiodon bathystoma* (Owen) from Oude Kloof, in the Nieuwveldt Mountains, Cape Colony, by Prof. H. G. Seeley, F.R.S. Two bones found by Mr. T. Bain at Oude Kloof consist of the left ramus of the mandible and what the author regards as the left squamosal bone of *E. bathystoma*. The small cranial fragment preserved shows that the cerebral region probably conformed to the type of skull seen in some of the Dicynodonts. A description of the remains is given, and the author notices that the form of the articular condyle indicates a difference from *Dicynodontia* and all other *Anomodontia* hitherto described; it implies an oblique forward inclination of the quadrate bone—a character important in defining the suborder *Endothiodontia*. All the characters of the dentition of the animal suggest near affinity with the *Theriodontia*, especially the long lanceolate teeth strongly serrated.—On the discovery of Mammoth and other remains in Endsleigh Street, and on sections exposed in Endsleigh Gardens, Gordon Street, Gordon Square, and Tavistock Square, N.W., by Dr. Henry Hicks, F.R.S. In this paper the author gives a description of the deposits overlying the loam in which the remains of the Mammoth and other animals were found in Endsleigh Street, N.W. Under about six feet of made ground there was about ten feet of a yellowish-brown clay containing flints and much "race." Below the clay there was about five feet of sand and gravel, and under this about one foot of clayey loam, in which most of the bones were embedded. This loam contained many seeds, recognized by Mr. Clement Reid as being those of plants usually found in marshy places or ponds, and having a range at present from the Arctic Circle to the South of Europe. A list of the bones found is given by Mr. E. T. Newton, of the Museum of Practical Geology, Jermyn Street, who describes them as being those of one full-grown Mammoth, of another about half-grown, of the Red Deer, the fossil Horse, and of a small rodent. The author gives sections through Endsleigh Street and along the southern side of Endsleigh Gardens, and shows that where the bones were found there was a distinct valley in the London Clay, running in a direction nearly due north and south, the inclination of the valley being towards the north. The London Clay reached nearest to the surface towards St. Pancras Church and in Upper Woburn Place, the total thickness of the overlying deposits and the made ground there being only about 12 feet. Other sections, given along the southern sides of Tavistock and Gordon Squares, and through Gordon Street and the western side of Gordon Square, show varying thicknesses of the deposits, overlying the uneven floor of London Clay, of from 16 to 21 feet; the greatest thickness here is found at the north-western corner of Gordon Square. Seeds were also discovered in a loam near the bottom of Gordon Street, at the same horizon as that containing the mammalian remains, and some shells were found in a band of sandy clay, under a calcareous deposit, about half-way down the western side of Gordon Square. The author says that the deposits above the mammaliferous loam overlying the London Clay in this area cannot be classed as post-Glacial river-deposits, but must be considered as of Glacial origin. The animals, therefore, which evidently died on the old land-surface where their remains were found, lived there early in the Glacial period. The reading of this paper was followed by a discussion, in which the President, Mr. Monckton, Sir Henry Howorth, and the author took part.—The morphology of *Stephanoceras zigzag*, by S. S. Buckman.

---

[1] Note by O. J. L.

Entomological Society, June 1.—R. McLachlan, F.R.S., Treasurer, in the chair.—The Hon. Walter Rothschild sent for exhibition *Neptis mimetica*, n.s., from Timor, mimicking *Andasena orope*, one of the Euplœidæ, and *Cynthia equicolor*, n.s., a species remarkable for the similarity of the two sexes, from the same locality; also a hybrid between *Saturnia carpini* and *S. pyri*, and specimens of *Callimorpha dominula*, var. *romanovii*, var. *italica*, and var. *donna*, bred by a collector at Zürich; he further exhibited a very large and interesting collection of Rhopalocera made by Mr. W. Doherty in Timor, Pura, Sumba, and other islands, during October and November 1891. Colonel Swinhoe remarked that the various species of *Neptis* were usually protected and imitated by other insects, and did not themselves mimic anything, and that the pattern of the *Neptis* in question was very common among the butterflies in the Timor group. Mr. Jenner Weir, Prof. Meldola, Mr. Trimen, and others continued the discussion.—M. A. Wailly exhibited fertile ova of *Trilocha varians*, which are arranged in small square cells, fastened together in large numbers, and present an appearance quite different from the usual type of Lepidopterous ova.—Mr. F. Merrifield exhibited a series of *Drepana falcataria*, half of which had been exposed for a week or two, in March or April, to a temperature of about 77°, and the other half had been allowed to emerge at the natural out-door temperature. The latter insects were in all cases darker than the former, all being equally healthy. Mr. McLachlan, Mr. Barrett, Mr. Jenner Weir, and others took part in the discussion which followed.—Mr. McLachlan called attention to the reappearance in large numbers of the Diamond-back Moth, *Plutella cruciferarum*, which was very abundant in gardens near London, and expressed his opinion that the moths had been bred in the country and had not immigrated.—Mr. Jenner Weir, Mr. Bower, and Prof. Meldola stated that they had recently seen specimens of *Colias edusa* in different localities near London.—The Hon. Walter Rothschild communicated a paper on two new species of *Pseudacræa*.

CAMBRIDGE.

Philosophical Society, May 30.—Prof. G. H. Darwin, President, in the chair.—The following communications were made:—The hypothesis of a liquid condition of the earth's interior considered in connection with Prof. Darwin's theory of the genesis of the moon, by Mr. Osmond Fisher. It was contended that a liquid condition of the earth's interior is not negatived by the existence of a semi-diurnal ocean tide, because it appears by calculation that a tide in an equatorial canal would in that case be diminished by only one-fifth of what its height would be upon a rigid earth. It was then recalled that all Prof. Darwin's numerical results in Table IV. of his paper on the precession of a viscous spheroid, as for instance that the moon was shed from the earth about 57 millions of years ago, depend upon the assumption of a certain high value for the internal viscosity, and will not hold good for a liquid interior. The total amount of heat, however, which must have been generated since that event, does not depend upon the viscosity, and will have been the same in the case of a liquid interior. This, if applied all at once, Prof. Darwin says, would raise the whole earth through 3000° F. if it had the specific heat of iron. Lord Kelvin holds that the earth is solid, and that it solidified in a short space of time, and that the matter of the interior at every depth is at the temperature of solidification for the pressure there. But if heat is being continually communicated to the interior, and chiefly to the more central regions, it seems impossible that the state of solidity supposed could be maintained. The author has shown in his "Physics of the Earth's Crust" that, if the crust is as thin as many geologists suppose, then there must exist convection currents in the interior, which prevent the crust from growing thick by melting off the bottom of it nearly as fast as it thickens. The central heat imparted to the interior by tidal action explains the maintenance of such currents. But the difficulty arises that the heat generated has been so great that there seems no obvious adequate mode of getting rid of it. The heat conducted away through the crust would not have been sufficient to reduce the mean temperature of the globe by more than about 209° F. in 100 million years from the first formation of a crust. Volcanic action on an extravagant estimate would help only to the extent of 4° or 5° F.; and the work of deformation of the crust would account for still less. It appears from the above that, if Prof. Darwin's theory is true, the solidification of the crust cannot have commenced until long after the birth of the moon; so that the still molten surface would be able for ages to radiate its heat directly into space. Otherwise we are thrown back on the nebular hypothesis, according to which the moon was left behind in the process of evolution of the system.—On Gynodiœcism in the Labiatæ, by Mr. J. C. Willis. Among the hermaphrodite flowers of *Origanum* and other Labiatæ, there occur (on the *same* plant) female flowers, and also flowers with one or more imperfect stamens; the corollas of these flowers are usually smaller than those of normal hermaphrodites. Their number varies from ·1 to 7·5 per cent. of the total flowers. Experiments conducted in 1891, to determine if these abnormalities varied in number with the season, gave no result; no two plants (though all were from one stock) gave similar results. Observations were also made on *Nepeta Glechoma*; the relative numbers of female and hermaphrodite flowers were determined weekly during the flowering season, and the proportion of females found to be greatest at the beginning of the season. It was also noticed that the female plants bear more open flowers at one time than the hermaphrodites (3·1 to 2·1). It was observed that the amount of protandry in the flowers appears to vary, being small at the beginning, and larger towards the end of the season. Further observations are in progress upon this subject.—On the steady motion and stability of dynamical systems, by Mr. A. B. Basset.—Note on the geometrical interpretation of the quaternion analysis, by Mr. J. Brill. The last two papers were taken as read.

DUBLIN.

Royal Dublin Society, May 18.—Dr. G. J. Stoney, F.R.S., Vice-President, in the chair.—Mr. G. H. Carpenter presented a report upon the Pycnogonida collected in Torres States by Prof. A. C. Haddon. The collection comprises only three species: *Pallene australiensis*, Hoek, for which (together with a new species) a new genus (*Parapallene*) is suggested; and a new *Ascorhynchus*.—Mr. H. H. Dixon gave a preliminary note on the mode of walking of some of the Arthropoda, illustrated by means of instantaneous photographs. He found that the limbs move together in "diagonals"; in insects the first and third legs on one side move with the second on the other; in spiders the first and third on one side with the second and fourth on the other; while the antenna of an insect is moved with the first leg on the same side.—Sir Howard Grubb, F.R.S., described his new chronograph for the Cape Town Observatory. This chronograph is built on the model of that at Dunsink Observatory, Dublin, with such improvements as have been suggested by recent developments in the clock-work of equatorial telescopes. The barrels, two in number, either or both of which can be brought into action, are 28 inches long and 9 inches in diameter. The screws which carry the wagons are one-tenth pitch, revolving once per minute. The circumference of the barrel being about 27 inches, the seconds are four-tenths of an inch long, and each barrel is available for about four and a half hours' work. The principal modifications upon the Dunsink instrument consist in the application of the electrical control of the clock, as described in the Proceedings of the Institution of Mechanical Engineers for the year 1888. The governor shaft of the clock gears directly into the driving spindle without any intermediate wheels, and as there is maintaining power to the clock barrel, it is possible to wind during the operation without at all affecting the rate of the clock. The axes of the barrels are supported upon sets of bicycle balls, in hardened steel boxes. The wagons carrying the electro-magnets for the registration of the signals are carried on one plain roller and two grooved rollers, the latter having hardened steel end-plates to insure accuracy of position. With the main instrument, which is inclosed in a glass case, is supplied a distributor for the purpose of working the electrical control, for the explanation of the action of which the above paper may be referred to.—On a new electrolytic galvanometer, by J. Joly. In the ordinary methods of determining the strength of a current by means of electro-chemical action, the element of time enters into the measurements, which further require considerable care in carrying out. In this instrument the observer is not concerned with time observations, and its indications follow fairly rapid variations of current. It consists of a glass bulb containing dilute sulphuric acid, in which are immersed platinum electrodes placed close together to diminish resistance. This vessel communicates below with a tube bent twice at right angles and carried up to a height of about 50 cm. above the level of the bulb. A little mercury contained in the bulb rises normally into this tube to a level which is the zero of the instrument. The tube is open at the top. The bulb is furnished with two tubulures on its upper surface. One is kept closed by a stopper, and merely serves to admit the electrolyte into the bulb when filling it. The other is furnished with a brass attachment upon which is cemented a small piece of platinum foil pierced by a hole of very small bore. The puncture is protected above and below from obstruction by receptacles containing cotton wool. When a current is passed between the electrodes the gas evolved can only escape through the fine puncture. At normal pressures this will only let the gas pass out slowly. Hence there is an accumulation of gas in the bulb, and the increased pressure causes the mercury to rise in the vertical index tube; but as the pressure rises, the rate of efflux of the gas increases till it equals the rate of evolution, when the mercury column comes to rest. The reading of a scale alongside the tube then gives the current in amperes. The instrument constructed for trial is very satisfactory. It reads on a very open scale up to 2·5 amperes. The electrodes are not large enough to carry heavier currents; if they were so, of course by enlarging the orifice the range could be increased. At the higher readings there is some delay before the mercury column becomes stationary, due probably to a rise of temperature in the bulb. There is probably some small variation of the readings with atmospheric temperature change. The calibration is effected by placing it in circuit with a trustworthy galvanometer. The inventor has had but little leisure to develop the instrument, and brings it before the Society in hopes that someone may think it worth while to further investigate its capabilities.

PARIS.

Academy of Sciences, June 7.—M. d'Abbadie in the chair.—On the application of M. Linstedt's method to the problem of three bodies, by M. H. Poincaré.—On a class of analytical functions of one variable, dependent on two real arbitrary constants, by M. Emile Picard.—On the products of the residual life of the tissues, especially of the muscular tissue separated from the living being, by MM. Gautier and Landi (continued). The authors found that meat when kept at a temperature not exceeding that of the living animal, acquired an acidity of about 0·5 per cent. after several weeks, during which it was protected from air and bacteria. They attribute this acidity to the formation of acid phosphate of potassium under the influence of fatty acids, and especially to the partial peptonization of the albuminoids. Two substances, found in milk, but not in fresh meat, are also abundantly produced, viz. casein and nucleo-albumin. The albuminoids steadily decrease, whereas there is a proportional increase of alkaloids, these being identical with those produced during the life of the organism.—Effects produced upon numerous morbid states by subcutaneous injections of a liquid extract from the testicles, by M. Brown-Séquard.—On the densities of liquefied gases and their saturated vapours, and on the constants of the critical point of carbonic acid, by M. E. H. Amagat.—On new methods of forming certain substitution imides, by M. A. Haller.—Reports of the Committee charged with the examination of the calculator Inaudi, by MM. Charcot and Darboux. Jacques Inaudi, a peasant born in Piedmont in 1867, learned to reckon before he acquired the art of reading and writing, which he did not master till twenty. He therefore owes his extraordinary calculating powers to an abnormally developed memory for figures, aided by a mental representation of numbers which the Committee proved by a series of careful experiments to be purely acoustical, and quite independent of visualization. The rules of Inaudi's operations are original. In addition and subtraction he begins on the left side, and deals with each whole number in its turn. The extraction of roots and the solution of equations are performed by tentative approximations, executed with remarkable rapidity. At the end of a long sitting Inaudi was able to recount the whole series of numbers dealt with, amounting to some 400 figures.—On the stability of motion in a particular case of the problem of three bodies, by by M. Coculesco.—Solar observations during the first quarter of the year 1892, by M. Tacchini. At the Roman College, during this period, the frequency of metallic eruptions, spots, and faculæ was greater in the southern hemisphere of the sun, whereas the protuberances were more frequent in the northern, and nearer the pole. The auroral maximum is probably more dependent on that of the protuberances than that of the sun-spots.—On a property common to three groups of two polygons, inscribed, circumscribed, or conjugate to one conic, by M. Paul Serret.—On discontinuous groups of non-linear substitutions with one variable, by M. Paul Painlevé.—On the acceleration of mortality in France, by M. Delauney. From a calculation based upon certain tables published by the Bureau des Longitudes, it appears that the death-rate is accelerated during the ages ranging from 16 to 32 and 54 to 82, while it is retarded between 1 and 16, 32 and 54, and after 82. This gives the numbers 16, 32, 54, and 82, which may be regarded as natural epochs of human life. They may be derived from the equation $3x^2 - 5x + 4$, by substituting for x the values 3, 4, 5, and 6. The equation represents a parabola.—Optical method of determining the conductivity of metallic bars, by M. Alphonse Berget. This is based upon an application of interference fringes or Newton's rings produced at the ends of two bars to be compared, by means of which the ratio of their elongations is found. Applicable to bars of rare metals.—On the propagation of heat within crystallized substances, by M. Ed. Jannettaz.—On a new determination of the ratio v between the electro-magnetic and the electrostatic C.G.S. units, by M. H. Abraham. Obtained by measuring the same capacity—of a plane condenser with guard ring—in both systems. The value obtained for v was $299{\cdot}2 \times 10^8$.—On the basic nitrates of zinc, by M. J. Riban.—On the permolybdates, by M. E. Péchard.—On a reproduction of leucite, by M. A. Duboin.—Contributions to the study of mineral waters: preservation of these waters, by M. P. Parmentier.—On the fixation of iodine by starch, by M. Gaston Rouvier.—Mechanical determination of the boiling-points of alcohols and acids, by M. G. Hinrichs.—Preparation and heat of formation of monosodic resorcin and hydroquinone, by M. de Forcrand.—Thermal study of the dibasic organic acids: methyl-malonic and methyl-succinic acids; influence of isomerism, by M. G. Massol.—On an oxidation product of starch, by M. P. Petit.—Organo-metallic combinations of the aromatic acetones, by MM. E. Louise and Perrier.—On the chlorine derivatives of the isobutylamines, by M. A. Berg.—Researches on the ptomaïnes in some infectious diseases, by M. A. B. Griffiths.—On the dioptase of the French Congo, by M. E. Lacroix.—Researches on the filtration of water by the Mollusca, and applications to ostreiculture and oceanography, by M. H. Viallanes.—On a parasite of the locusts, by M. L. Trabut.—Tuberculous vaccination of dogs, by MM. Héricourt and Ch. Richet. The effect was tried of vaccinating some dogs with aviary tuberculosis, which proved a perfect prophylactic to human tuberculosis, the injection of which proved fatal to those not so vaccinated, the rest being unaffected.

BERLIN.

Physiological Society, May 13.—Prof. Munk, President, in the chair.—Prof. Loewy gave an account of experiments on respiration under reduced atmospheric pressure, carried out in a confined space which admitted of very rapid reductions of pressure (to half an atmosphere) with constant composition of the inclosed air. The amount of reduction which was borne without ill effects differed in the case of the three persons on whom the experiments were made, in accordance with the magnitude of their respiratory activities: the greater the latter, the greater was the reduced pressure which could be withstood. For any one person it appeared that a greater reduction could be borne while fasting or during work than after a meal or during repose. Both oxygen and carbon dioxide were found to do away with the discomfort resulting from over rarefaction of the air. Slightly reduced pressure had no effect on respiratory interchange, while if the reduction was considerable, more carbon dioxide was expired, notwithstanding the diminished supply of oxygen. The reduced pressure of the latter gas was found to act on the respiratory mechanism in such a way as to lead to deeper, and hence compensatory, respiratory movements.—Dr. Wertheim spoke on the blood-vessels of the avian eye in both the embryonic and fully developed state, illustrating his remarks by injected specimens of embryonic eyes.

Physical Society, May 20.—Prof. Lampe, President, in the chair.—Prof. Neesen gave an account of his researches on the motion of loose disks centred on an axis rotating at high speeds. The disks were of varying mass and moment of inertia, and had at one side an excentrically-placed pin, in order that the least weight might be determined which, when applied to this pin, stopped the rotation of the disk. The necessary weight, as thus measured, was found to vary with the rotational velocity of the axis and with the mass and moment of inertia of the disk. It varied also according as the axis was dry or smeared with old or new oil, and also with the material of which the disk was made, &c.—Dr. Wien spoke on Maxwell's electro-magnetic theory, and the additions made to it by Poynting, and gave, in conclusion, a hypothetical conception of the nature of magnetism which corresponded to the existing formulæ.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Notes and Queries on Anthropology, second edition: edited by J. G. Garson and C. H. Read (Anthropological Institute).—The Birds of the Sandwich Islands, Part 3: S. B. Wilson and A. H. Evans, (Porter).—Irrigation and Water Storage in the Arid Regions; Letter from the Secretary of War (Washington).—Die Grundzüge der Theorie der Statistik: Prof. H. Westergaard (Jena, Fischer).—Die Bewegung der lebendigen Substanz: M. THE NEW LONDON UNIVERSITY.

IN our last issue we laid before our readers a statement of the proposals adopted by the Association for Promoting a Professorial University for London at a meeting held at Burlington House on the 14th inst. It may tend to clear the issue if we now briefly compare these proposals with the provisions of the Gresham Charter.

The Gresham Charter seeks to federate two Colleges and ten medical schools, primarily for examination purposes. Such a University, if created, would have had two competing staffs in the Faculties of Arts and Science and twelve in the Faculty of Medicine. Provision is also made, under certain conditions, for the federation of other institutions, if it can be shown to the satisfaction of the Council—that is, of the Chancellor, the Lord Mayor of London, and the representative members of the Councils of the two constituent Colleges and the ten medical schools—that such institutions are on a basis justifying the expectation of permanent existence; that they are under the independent control of their own governing bodies; and that they are reasonably well equipped in some one Faculty. Such a federation, created not primarily for the true business and proper functions of a University, but solely in the interests of a degree-granting body, could only have one result. The examination schedules must perforce be within reach of the lower grades of instruction, the various constituent elements would be actively competing bodies, and no attempt to create a single competent staff and a single set of fully-equipped University laboratories would be feasible. Is it at all probable that the true work of a University would flourish under such a system as that? Is it in the least degree likely that we could hope to see created in London, a teaching organization worthy of the greatest and richest capital in the world, or even such as many of the smaller European capitals now possess? The fame of a University, if it is to be anything more than a social function, must depend on the character of its teaching. Would the best men be attracted and retained by such a system? There can be only one answer to these questions. The Gresham scheme is not only a wholly inadequate solution of the University question, but in so far as it tends to accentuate and perpetuate the existing state of things its provisions are positively mischievous. No solution of the question can be either just or final which ignores the existence of the present University of London. If London is to have two degree-granting bodies existing, practically, side by side, we shall have confusion worse confounded. Burlington Gardens would inevitably be driven to establish a teaching organization of its own, unless it was supremely indifferent to its fate or supinely content with the teaching of the Correspondence Colleges and the crammers. Why should we neglect, and not only neglect but positively so arrange as to destroy, the prestige of the existing University of London? This University is not effete—it has still within it a great potentiality for good. Surely, in common gratitude, the University which has hitherto consistently upheld a high standard of attainment for its degrees, and which has done so much for the spread of natural science in this country, is worthy of better treatment at the hands of those who profess to minister to the true interests of learning. The Gresham scheme is really an attempt on the part of certain of the medical schools and some of the arts and science teachers to cheapen degrees and so attract students. It is true that the new University medical degrees would carry no license to practise. But is it likely that the University would permanently put up with this unique position, or that its students would continue to submit themselves without a murmur to a double examination system? As the document issued by the Victoria University indicates, the result, in all probability, would be to reduce the two examinations to a single standard by compromise with the licensing body. The scheme, moreover, gives an overwhelming preponderance to the most purely professional of all the faculties, and far too large a share of control to persons of small academic experience who devote occasional spare hours to academic affairs. It makes no attempt to satisfy the demand for the recognition in some form of University work among the people. No wonder, then, that it was strenuously opposed by a powerful section of the governing body, and by a majority of the teachers in the Faculties of Science and Arts, of the most influential College that it proposed to incorporate. The Council of University College, indeed, has never openly ventured to place the scheme before the governing body.

The Gresham University Commissioners are authorized by the terms of their reference "to consider and, if they think fit, to alter and to amend and extend the proposed charter, so as to form . . . a scheme for the establishment, under charter, of an efficient teaching University for London." It is impossible to conceive how the charter submitted to them can be amended so as to form such a scheme if its salient features are preserved. That fact is becoming more and more patent every day. The Association which put forward the proposals we have already referred to now numbers among its members—medicine excepted—a majority of the leading London teachers. If these teachers say that they do not wish the Gresham Charter at any price, it is difficult to see how it can be imposed upon them. Any attempt to resuscitate that charter, even with amendments, will meet, as before, with the opposition of the provincial Colleges, the minor London teaching bodies, and, what is perhaps more important, the organized opposition of a large section of the London teachers, and of some of the most powerful and influential friends of higher education in this country.

The fact is that it is at last clearly recognized that the foundation of a Metropolitan University, which will bear comparison with those of the great Continental cities, is a matter of national importance. The action of the House of Commons with regard to the Gresham Charter offers an opportunity, such as may not soon occur again, for attempting the formation of a University in London on the same ample lines as those to be found in other European capitals. Watchful observers of what has been going on during the past three or four years have deliberately come to the conclusion that it is quite impossible to improve the condition of higher education in London by means of any federation of Colleges. The creation of a homogeneous academic body with power to *absorb*, not to federate, existing institutions of academic rank, is the only real solution of the problem. An academic body of this character might well be organized, so far as teaching is concerned, on the broad lines of a Scottish University. Such a corporation may be conveniently spoken of as a *professorial University*, to distinguish it from a federal University. A federal University may be all that is possible when the constituent Colleges are situated in different towns, as is the case in the Victoria University; but it cannot be efficient in London, where these Colleges would appeal to the same public for support.

The scheme put forward by the Association for Promoting a Professorial University for London is not open to the objections urged against the Gresham scheme. It would found a University on the same broad lines as those of France, Germany, and Switzerland. It would bring to the new University all the power and prestige of the existing University. It will meet with no opposition from the provincial Colleges; on the contrary, it has the active support of many of the leading provincial teachers. It satisfies the demands of the Victoria University that the medical degree shall carry the license to practise, and that the medical representation shall not preponderate. It has, for the first time in the history of the movement, brought the most influential teachers from a variety of London teaching bodies into close and active sympathy, and animated them with a desire for a University of definite type. It is significant that the Council and staff of Bedford College are at one in favour of a University on the general lines laid down in the Association scheme. The Senate of University College has carried a motion urging their Council to adopt a similar resolution in favour of the scheme of absorption. The Association scheme makes full provision for the recognition of work of the University Extension character, and for the appointment of University lecturers at minor and non-absorbed teaching institutions. Whilst proposing central control and central University laboratories of the highest type, it provides for local teaching such as is required for pass degrees or for the lower stages of honours graduation. Lastly, it provides for post-graduation courses and specialized instruction, such as that of the Collège de France and of the greater German Universities.

As regards medicine, it recognizes that it is impossible to "absorb" the medical schools owing to their close relation to great public charities; but at the same time it endeavours to grant much of what the Medical Faculty gained by the Gresham Charter. The Medical Faculty will be elected by the medical teachers themselves. There will be, as in every University of standing, medical professors appointed by the Senate from the Medical Faculty on the recommendation of the faculty. The existence of such a medical professoriate will enhance the dignity of the University and of the medical schools, whilst at the same time it holds out a strong inducement to those schools to select members for the Medical Faculty on the ground of their scientific as well as their administrative reputation. The limitation of the number of medical professors on the Senate will safeguard the character of the medical degree. The scheme, whilst giving very extended powers to the medical schools, meets the objections of the provincial opponents of the Gresham Charter. Lastly, it provides for the due University recognition of the pure science teaching of the medical schools.

We have thus indicated as shortly as possible the main features of the two schemes which are at present before us. The one is essentially parochial in its conception, and vestry-like in its character. The other has in it the elements of a great teaching organization which shall be both metropolitan and imperial in its aims and influence—a University which shall be worthy of London, the capital alike of Great Britain and of the Greater Britain beyond the seas.

THE ANALYSIS OF WINES.

Analyse des Vins. Par le Dr. L. Magnier de la Source. (Paris: Gauthier-Villars et Fils, 1892.)

ALTHOUGH wine is gradually becoming more and more important as an item in the national drink-bill—last year we imported 16,782,038 gallons, valued at £5,995,133—its analysis and the methods for the detection of its sophistication have received comparatively little attention from the chemists of this country. On the other hand, in France and Germany the subject has been very thoroughly investigated in practically all its many details, and carefully worked-out methods have been prescribed for the guidance of the public analysts of those countries. Indeed, there is probably no article of food or drink, with the possible exception of milk, of which the chemistry has been so well thrashed out. Wine is in reality a highly complex fluid, and on account of the character of certain of its proximate constituents it is frequently liable to change. It contains various alcohols, glycerin, acids, salts, "extractive matter," together with those principles which give to it its particular colour, special flavour, smell, or "bouquet." Whilst some of these constituents can be accurately isolated and described, others can only be detected by the sense of smell. The principal alcohol is, of course, ethyl alcohol, but butyl and amyl alcohols, together with ethylene glycol and isobutyl glycol are not unfrequently present in greater or less quantity. The quantity of alcohol in natural wines may be said to vary from 6 to 12 per cent., and the quantity of glycerin from 7 to 10 per cent. of the alcohol present. Tartaric, malic, succinic, glycollic, and oxalic, together with tannic and acetic, are the chief acids in wine. These are said to aid in its preservation, by preventing the formation of fungi. Traces of other fatty acids, such as propionic, butyric, and œnanthic acids are also present, as well as acetaldehyde, and possibly its homologues. Tartaric acid occurs mainly as the dextro variety: lævo-tartaric acid is only of comparatively infrequent occurrence. If tartaric acid is not found, as, for example, in certain samples of sherry, its absence is almost certainly due to its removal by "plastering." The amount of free acid in sound wine, reckoned as tartaric acid, varies between 0·3 and 0·7 per cent.; a greater amount than this imparts sourness to the wine.

Old wines have an acid reaction in consequence of the presence of a certain amount of free acid and potassium bitartrate. A wine not exhibiting this acid reaction tastes flat; the acidity is its most important flavour. For a long time it has been believed that the free acid of wine is tartaric acid alone. Nessler's researches have, however, shown that this is seldom the case; tartaric and malic acids often exist together, and frequently the free acid consists of malic acid entirely. Wines containing tartaric acid taste more tart than those with only malic acid, or a mixture of malic and tartaric acids.

The characteristic smell of wine is said to be due to œnanthic ether; the compound ethers probably confer the bouquets which distinguish one vintage from another: among these are aceto-propylic, butylic, amylic, caprylic, butyro-ethylic, caprylo-ethylic, capro-ethylic, and pelargo-ethylic, and the tartaric ethers. According to Jacquemin, these bouquets are primarily due to the special characters of the yeast used in the several districts. One and the same "must" fermented with the yeast obtained from several different districts gave wines having the bouquet characteristic of the district from which the particular yeast had come. Rommer fermented the juice of an inferior grape and of hot-house grapes respectively with yeast cultures obtained from the Champagne, Côte d'Or, and Buxy districts, and found that in each case the wines had the bouquet of those from which the yeast had been derived. The sugars occurring in wine are dextrose and lævulose. Cane-sugar is never naturally present, even in "must"; it is sometimes added, as in the case of champagne, but it is then rapidly transformed into invert sugar. In some wines, as, *e.g.*, Sauternes and sweet Rhine wines, sugar occurs in the form of inosite. The colouring-matter of normal wine is derived partly from the oxidation of the so-called extractives contained in the juice, and in the case of red wines from matter (œnolin or œnotannin) contained in the husks, stalks, and seeds, which is soluble only by the joint action of acid and the alcohol formed during fermentation. The albuminous substances in the "must" are removed when the fermentation is properly carried out, but in imperfectly fermented wines a certain amount remains, and in the case of white wines may again render them liable to fresh fermentation. In red wines this danger is obviated by the presence of the tannin of the husks.

The inorganic substances contained in wine are potash, soda, lime, and magnesia, in combination mainly with tartaric, phosphoric, and hydrochloric acids. Sherries contain potassium sulphate in excess, owing to the practice of adding gypsum to the "must." This practice, which prevails not only in Spain, but also in Portugal, the south of France, and to some extent in Italy, probably has for its object the precipitation of certain albuminous matters which injuriously affect the wine. It is alleged that the fermentation is in consequence much more rapid and complete, that the wine keeps longer, and that its colour is richer and more lasting. Its real advantage to the wine-maker is that it clarifies the wine rapidly, and allows it to be quickly brought to market. It is chiefly employed with the coarser qualities of red wine, and the gypsum is either added to the grapes and trodden with them, or, in fewer cases, added to the expressed juice; the quantity used is generally 1 to 2 kilos to every 100 kilos of fruit, but it is some times as much as 10 kilos. The action of the calcium sulphate on the bitartrate of potash present in the juice produces an acid sulphate of potash, which gradually forms the normal salt by decomposition of the phosphate present forming free phosphoric acid. Hence a "plastered" wine is relatively rich in potash and sulphuric acid.

Although much has been said as to the baneful effects of plastered wine, very few trustworthy cases of injurious action have been recorded. The Academy of Medicine of Limoges instituted a lengthened inquiry on the subject in 1888, and reported unfavourably on the effects of plastered wine upon health. The French War Department also appointed a Commission, and its conclusions, which, on the whole, were unfavourable to the practice, have been recently confirmed by Nencki, who was requested by the Government of the Canton Berne to report on the advisability of modifying a law, which operates in many parts of the Continent, forbidding the sale of wines containing more than 2 grams of potassium sulphate to the litre. As to the question whether a plastered wine should be called adulterated, it has been contended that a product which, by treatment, is deprived of one of its most characteristic constituents, viz. tartaric acid, whilst another substance, calcium sulphate, not normally present, is introduced, cannot be called anything but adulterated.

As may be supposed, the art of the falsifier is very largely directed to the improvement of the colour of wine; and unfortunately it is upon the product which popular prejudice associates with the name of an eminent statesman, and which has no other attribute of claret than its colour, that his skill is mainly expended. It has been estimated that the whole yield of the "classed growths" of the Médoc does not, even in the best years, now exceed 5,000,000 bottles. Much of this, it is true, comes to England, but enormous quantities of *paysan*, *artisan*, and *bourgeois* wines from the Gironde and Languedoc, mixed with the produce of North Spain and Italy, are worked up and sold as "claret" in this country. This product is not exactly poisonous, nor even, as a rule, positively hurtful, but, it need hardly be said, it has no special merit or individuality. Formerly, the pharmacopœia of the wine-doctor, like that of the physician of old, was restricted to products of the vegetable kingdom; but, in addition to the colouring-matter of *Phytolacca* berries, *Althæa rosea*, bilberries, mallow, elderberries, privet-berries, logwood, alkanna red, lichen reds, all of which are still used to a greater or less extent, he has not been unmindful of the wealth of colouring-matter which is latent in coal-tar; and to-day the banks of the Rhine have their part in the manufacture of other wines than hock. Biebrich scarlet, fuchsine (magenta), the various Ponceaus, Bordeaux reds, crocein scarlet, and similar colouring-matters, find their way to the south of Europe for the purpose of wine sophistication. A substance known as *tintura per los vinos* is largely used in the district of Huesca for colouring Spanish wines. It contains two coal-tar derivatives, one of which is that form of Biebrich red which is turned blue by sulphuric acid, whilst the other, which exists in smaller proportion, closely resembles the colouring matter known as *cerise.* According to an analysis by Jay, the composition of *tintura* is: organic matter, mainly Biebrich red, 66·4; sodium sulphate, 26·10; arsenious oxide, 1·62; iron oxide, lime, &c., 5·88. In view of the peculiar nature of this substance, it is reassuring to know that there is a tendency to return to vegetable colouring-matters, and that large quantities of maqui berries are being imported into Europe from Chili for the purpose of colouring wines. In the three years ending 1887 the exports of this substance were respectively 26,592, 136,026, and 431,392 kilos, by far the largest proportion finding its way to France.

The little book before us has no pretensions to be regarded as a complete treatise on the analysis of wines. Its aim is to furnish the analyst with a number of carefully tested methods for the detection of sophistications and adulterations, and for the rapid determination of those constituents on which the character of wine mainly depends. Dr. Magnier de la Source is well known in France as an authority on the subject, and the *Bulletin* of the French Chemical Society contains papers by him relating to the analysis of wine. His methods are, for the most part, similar to those adopted by the Association of German and Austrian analysts, although they are not described with that minute attention to detail which has been found desirable by the German-speaking chemists. As may be seen on turning over the pages of Fresenius's *Zeitschrift für analytische Chemie*, the "musts" and wines of Germany are periodically examined and reported upon with all the method and regularity adopted in the case of the London water-supply; and it has happened in the past that the modes of determining such constituents as the vegetable acids, glycerin, and "extractive matters" have been discussed and wrangled over in a manner which recalls the famous fights over "organic carbon," "albuminoid ammonia," and "previous sewage contamination" of years ago. The only fault that we have to find with this book is that its author hardly does justice to his German brethren; although, it is but fair to add, some reference to their work is to be found in the excellent bibliography at the end of the volume. T. E. T.

MODERN THERAPEUTICS.

An Introduction to Modern Therapeutics. By T. Lauder Brunton, M.D., &c. (London: Macmillan and Co., 1892.)

THIS work is a reprint of the Croonian Lectures delivered before the Royal College of Physicians, London, in 1889. Whatever Dr. Brunton writes is sure to be interesting, and the present lectures have lost none of their lucidity or freshness though three years have elapsed since they were before the medical profession. It is hardly necessary to say that the subject is one with which Dr. Lauder Brunton is eminently fitted to deal, and the non-medical reader will be convinced when he has read the volume that medicine and therapeutics are far from being the inexact sciences they were not many years ago. The elementary nature of some of the early pages will be understood when it is remembered that the audience before which the lectures were originally given consisted in a large measure of men who had learnt chemistry before the days of Crookes, Lockyer, and Mendeleeff. It was necessary that the author should lead them through a brief survey of the chief facts and theories relating to atoms and molecules until the more difficult subject of the composition, constitution, and methods of union of organic radicles is reached. This is done in an admirably clear summary, assisted by those apt illustrations drawn from every-day life for which Dr. Brunton is so well-known. Our new drugs are now made by the chemist; so great has been the advance of organic chemistry, that the pharmacologist has hard work to keep pace with all the new combinations that issue from the laboratory. But the two classes of investigators, the chemists and the experimental therapeutists, have at least gone hand in hand so far, that it is now possible to judge the action of a drug by its composition. This, however, as Dr. Brunton points out, is not a rule without exception. There are many drugs which behave in unexpected ways; they no doubt, in the future, will be brought into harmony with laws of nature yet to be discovered. At present it is not possible to prophesy the physiological action of a chemical compound with that mathematical accuracy which enables astronomers to foretell eclipses; pharmacology is yet, and perhaps always will be, an experimental science.

The lectures stand practically in the same condition as that in which they were delivered. A volume of equal size to that under consideration would have been necessary to include all the new work that has appeared in the last few years. The tuberculin of Koch; the importance of poisonous proteids, and the diminishing popularity of the ptomaines; the action of the intestinal epithelium (*vice* the liver) as the gatekeeper protecting the body from the entrance of albumose; the application of phagocytosis to the problems of disease, together with the views of the antiphagocytists—these are a few of the big questions that have come to the fore in the last three years, and it is only active pathologists who would be able to realize how much longer these lectures would have been if full reference had been made to all of them. The main facts, and the principal conclusions adduced by Dr. Brunton, will, however, still remain; and all those who read the lectures in the medical journals before will welcome their appearance in a more permanent form now, and to those who missed them in 1889 we can confidently recommend the book as one which will not only be interesting but also useful. W. D. H.

OUR BOOK SHELF.

Elementary Hydrostatics. By W. H. Besant, Sc.D., F.R.S. "Cambridge Mathematical Series." (Cambridge: Deighton, Bell, and Co., 1892.)

THE success this work has achieved will be gathered from the fact that this is the fifteenth edition, so that any further criticism on our part would be quite unnecessary. The brief snatches of historical matter, together with the lucid and simple explanations, all tend to stir up in the student an amount of interest which in the reading of many other works on this subject lies dormant. By a careful study of the illustrations, especially those relating to pumps, presses, &c., the beginner may gather much knowledge about the principles on which they are based. In this edition the text has undergone a careful revision, several alterations and additions having been made. A uniform system of units has been maintained throughout, and the chapters on the motions of fluids and on sound, which in previous editions were inserted among those on the equilibrium of fluids, have here been separated. The examples and problems at the termination of each chapter are as numerous as ever, a new edition of their solutions being near completion. Both at the Universities and elsewhere, the work will still continue to occupy the high position which it has held among treatises of its kind. W.

The Threshold of Science. By C. R. Alder Wright, F.R.S. Second Edition, Revised and Enlarged. (London: Charles Griffin and Co., 1892.)

THE primary aim of this book is to interest young readers in various simple and amusing experiments, illustrating some of the chief physical and chemical properties of surrounding objects, and the effects upon them of light and heat. In the present edition the author has made no change which is likely to interfere with this object, but he has added various scientific appendices, and an excellent chapter on the systematic order in which class experiments should be carried out for educational purposes. These additions will be of great service to all who may wish to use the volume not merely as a "play-book," but as an instrument for the training of the mental faculties. Any one who may still have doubts regarding the value of elementary science as an organ of education, will speedily have his doubts dispelled if he takes the trouble to understand the methods recommended by Dr. Alder Wright. The majority of the experiments he has selected must not, of course, be studied merely in his exposition. It is intended that each reader shall make them himself. If that is done, they cannot fail to quicken the intelligence even of "the average boy."

Key to J. B. Lock's Elementary Dynamics. By G. H. Lock, M.A. (London: Macmillan and Co., 1892.)

THIS key will be found most useful both to beginners and teachers alike. The examples are all carefully worked out, many of the more difficult problems being treated at greater length with the view of helping those who are studying without the aid of a teacher. By an intelligent use of this book, a student should acquire a good knowledge of the method of working out problems as well as the important factor of attacking them in the right way. W.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Ice in the South Atlantic.

THE following account of ice met with in the South Atlantic at the commencement of last April, which has been supplied to the Meteorological Office by Captain Froud, of the Shipmasters' Society, may be of interest to your readers.

ROBERT H. SCOTT,
June 17. Secretary, Meteorological Office.

Ship *Cromdale*, London.

SIR,—I now send you a short account of my unusual encounter with ice in the above ship on our homeward passage from Sydney.

We left Sydney on March 1, and having run our easting down on the parallel of 49° to 50° S., rounded the Horn on March 30 without having seen ice, the average temperature of the water being 43° during the whole run across.

At midnight on April 1, lat. 56° S., long. 58° 32′ W., the temperature fell to 37°·5, this being the lowest for the voyage, but no ice was seen, although there was a suspicious glare to the southward.

At 4 a.m., April 6, lat. 46° S., long. 36° W., a large berg was reported right ahead, just giving us time to clear it. At 4.30, with the first sign of daybreak, several could be distinctly seen to the windward, the wind being north-west, and the ship steering north-east about nine knots. At daylight (5.20) the whole horizon to the windward was a complete mass of bergs of enormous size, with an unbroken wall at the back; there were also many to the leeward. I now called all hands, and after reducing speed to seven knots, sent the hands to their stations and stood on. At 7 a.m. there was a wall extending from a point on the lee bow to about four points on the quarter, and at 7.30 both walls joined ahead. I sent the chief mate aloft with a pair of glasses to find a passage out, but he reported from the topgallant yard that the ice was unbroken ahead. Finding myself embayed, and closely beset with innumerable bergs of all shapes and sizes, I decided to tack and try to get out the way I had come into the bay. The cliffs were now truly grand, rising up 300 feet on either side of us, and as square and true at the edge as if just out of a joiners' shop, with the sea breaking right over the southern cliff and whirling away in a cloud of spray. Tacked ship at 7.30, finding the utmost difficulty in keeping clear of the huge pieces strewn so thickly in the water, and having in several cases to scrape her along one to get clear of the next. We stood on in this way till 11 a.m., when to my horror the wind started to veer with every squall, till I drew quite close to the southern barrier, having the extreme point a little on my lee bow. I felt sure we must go ashore without a chance of saving ourselves. Just about 11.30 the wind shifted to the south-west with a strong squall, so we squared away to the north-west, and came past the same bergs we had seen at daybreak, the largest being about 1000 feet high, anvil-shaped, and at 2 p.m. got on the north-west side of the northern arm of the horse-shoe shaped mass. It then reached from four points on my lee bow to as far as could be seen astern, in one unbroken line. A fact worthy of note was that at least fifty of the bergs in the bay were perfectly black, which was to be accounted for by the temperature of the water being 51°, which had turned many over. I also think that had there been even a small outlet at the eastern side of this mass the water between the barriers would not have been so thickly strewn with bergs, as the prevailing westerly gales would have driven them through and separated them.

I have frequently seen ice down south, but never anything like even the smaller bergs in this group. I also had precisely the same experience with regard to the temperature of the water in our homeward passage in the ship *Derwent* three years ago, as we dipped up a bucket of water within half a mile of a huge berg and found no change in the temperature.

I trust you will warn, as far as possible, those about to sail for the Cape, as these bergs must soon reach that part.

I remain, yours truly,
(Signed) EDGAR H. ANDREW, Master.
June 12.

Land and Freshwater Shells peculiar to the British Isles.

MR. COCKERELL, in his article in NATURE of May 26 (p. 76), draws attention to a list of land and freshwater shells peculiar to the British Islands in Dr. Wallace's new edition of "Island Life." This work is of such very great importance to every one engaged in the study of the geographical distribution of animals, that it is regrettable the author should have repeated an error made in the first edition. *Geomalacus maculosus*, as is mentioned in Mr. Cockerell's article, is not peculiar to the British Islands. A specimen was discovered in Northern Spain as far back as 1868 by Mr. von Heyden, and recorded in the *Nachrichtsblatt d. deutschen Malakozool. Gesellschaft* by Heynemann in 1869. The allied species, supposed to have been found in France, has been proved to be an Arion; but several species of the interesting genus Geomalacus have been recently described by Simroth from Portugal.

Mr. Cockerell also states that several varieties in the list of peculiar British forms may have to be eventually struck out; and this is certainly the case, as the variety *albolateralis* of *Arion ater*, mentioned as "very distinct," was found near Bremen, in Germany, and is described in Simroth's "Naturgeschichte der deutschen Nacktschnecken" (*Zeitschr. f. wiss. Zoologie*, vol. 42, 1885). R. F. SCHARFF.

22 Leeson Park, Dublin, June 13.

THE IMPERIAL INSTITUTE.

THE Imperial Institute is no longer a castle in the air, an abstraction the meaning of which is to be guessed at through a veil of mist, but a solid and handsome structure, affording a pleasant contrast to those in its immediate vicinity.

The objects and purposes which this institution should fulfil have been fully ventilated and discussed in these columns ever since the idea of such a national memorial, commemorative of the fiftieth year of the reign of Her Majesty, was suggested. This being so, it will be interesting to many of our readers if we make one or two comparisons of the scheme as it exists at present with the past suggestions. In an article on "Science and the Jubilee" in 1887 (NATURE, vol. xxxv. p. 217), we wrote:—

". . . . There is room for an Imperial Institute which might without difficulty be made one of the glories of the land, and which would do more for the federation of England and her colonies than almost any other machinery that it is possible to imagine. But it must be almost exclusively a scientific institution. Its watchwords should be 'Knowledge and Welcome.' England, through such an institution, should help her colonies in the arts of peace, as she does at present exclusively in the arts of war. In an Imperial Institute we can imagine the topography, the geology, the botany, and the various applications of science, and the industries of Greater Britain going hand in hand."

Again, referring to the proposed inclusion of an Emigration Office in the scheme, it was remarked:—

"With this we cordially agree. But the return current must be provided for. Those who have lived in England's colonies and dependencies know best the intense home feeling, and in many cases the stern necessity there is of close contact with the mother country. Let the Imperial Institute be England's official home of her returning children—the hall in which she officially welcomes them back. Let them here find all they need, and let information and welcome be afforded with no stinted hand."

An inspection of the parts already ready for occupation in the new building took place on Saturday last, and we confess frankly that the idea of "Welcome" referred to in the preceding paragraph has been fully carried out. The building is admirable architecturally, and in the various halls set apart for the purpose the children of the Greater Britain beyond the seas will find no unworthy home when they visit the mother country. Their intercourse will not be confined to meeting each other; the proposal to create home Fellows of the Institute will, no doubt, be taken advantage of by all interested in all the larger questions on which the progress of the Empire must depend. By this means an Imperial Club of a very real kind has been created.

So far, then, as one of the watchwords, "Welcome," is concerned, there is cause for sincere congratulation. It is too soon to discuss the many proposals regarding the other watchword, "Knowledge," with the future activity of the Institute in the second direction. The lines of activity already actually taken up and provided for in the building as now arranged may be gathered from a glance through the pages of the pamphlet and papers distributed on Saturday.

The contents of the galleries will constitute "a living representation of the resources of the Empire and of the condition of its industries and commerce." The permanent collections will illustrate "the natural and industrial products of the United Kingdom, of the several Colonies, and of India," while, from time to time, occasional exhibitions will be held which will, "it is hoped, stimulate and enlist the sympathies of Colonial, Indian, and British producers, and promote active co-operation with the industrial section of the Empire."

The collections will be arranged and described in such a manner as to afford full "scientific, practical, and commercial information relating to the sources, nature, facilities of supply, and applications of well-known natural products, and of those whose industrial or commercial value still needs development." The libraries, offices of reference, reading-rooms, &c., in conjunction with the above exhibits, should form therefore a mine of wealth. We note also an arrangement by which samples of products will be given to anyone who may be desirous of obtaining specific information respecting any particular product included in the collection.

Ample opportunities are to be offered for conference on matters of common interest, and for the interchange of information relative to both Great and Greater Britain.

Such, then, are some of the points included in the preliminary arrangement of the building. No one, we suppose, considers them as final. Natural selection will come in, and it rests with the representatives of the scientific bodies among the governing body to determine which parts of "Knowledge" of the higher kind shall be fostered. This is a problem for the future. We need not stop to consider it now.

One word about the building itself and the allocation of space.

Passing through the principal entrance, which is constructed altogether of Portland stone, the large reception hall is reached, which, when finished, will constitute one of the finest we have, various marbles and Indian teak panelling being profusely used.

The principal floor contains in its western corridor the British-American and British-Australasian conference rooms, the council chamber, and the secretarial and clerical offices; and in the eastern corridor the British-Indian and British-African conference rooms, the writing, reading, and news rooms, and the temporary library. The principal stairway, leading to the second floor, will, when finished, be a handsome piece of work; the steps will be of Hopton Wood stone, with marble balusters and rails, while the walls will be lined with specimens of British and Colonial marbles, and the ceiling profusely decorated with arabesque plaster.

On the first floor the Fellows' dining and reading rooms are situated. The rooms in the east corridor, occupied at present by a very interesting exhibition of Indian art metal work, will subsequently be used for the commercial department and commercial conferences. In the west corridor various rooms will be put at the disposal of various Societies "whose objects are kindred to those of the Imperial Institute."

On the second floor will be situated the public dining and refreshment room. Here also the rooms in the west corridor and on the south side will be used as sample examination rooms: there will also be a map room and a Fellows' smoking room. The east corridor will, we are somewhat ambiguously informed, be occupied probably by "certain Societies who are seeking the splendid accommodation which the Institute affords for carrying on their work." When these Societies are named, the policy of the governing body in this direction will become more obvious.

TIME STANDARDS OF EUROPE.

THE era of world time is yet far off, and it is certain that the desirable scheme for a uniform horary standard put forward by the Astronomer-Royal (NATURE, vol. xxxiii. p. 521) will not be realized this century. But though this be so, signs of better times in the reckoning of the hours of the day have recently appeared, and the practical outcome of the Prime Meridian Conference at Washington (NATURE, vol. xxxiii. p. 259) is already of importance. Time is a problem to us all—a problem which has baffled the philosopher, driven the astronomer to devices which closely resemble subterfuges, and harassed the watchmaker beyond all other craftsmen. Much light on the difficult but all-important question is focussed in Mr. Lupton's article in NATURE, vol. xxxix. p. 374; but education will do more than it has yet done when the average man succeeds in understanding what he cannot but believe, that forenoon events in Australia are printed in British newspaper offices before daylight on the day they occur, while morning doings in Hawaii cannot fly fast enough by cable to catch the latest edition of the evening papers. In strict justice the time of no two meridians should be the same; and as a matter of fact, in pre-railway days every town, and every garden large enough to boast a sun-dial, set itself by its own local time. Railways have made the uniformity of time within narrow belts of longitude a necessity, and so largely does the railway affect modern civilized life that railway time soon comes to regulate all affairs. The vexation of frequent changes of time standards is familiar to all who have travelled on the Continent, and for many practical purposes the change which has been quietly progressing for the last few years is a benefit of great value. This change was brought home to the dwellers in Belgium and the Netherlands on May 1, 1892, by the retardation of all the railway clocks by from ten to twenty minutes from local to Greenwich time, an alteration of the time-gauge of two countries far more significant than the conversion to standard gauge of the railways of England.

At the Poles, where all meridians converge, there can be no natural standard time, for it is every hour of the day at once; but the regulation of time at these singular points has not yet become a burning question. Were the system of time-reckoning recommended by the Prime Meridian Conference carried out in its entirety, the minutes indicated on all well-regulated clock-dials throughout the world would be the same at a given instant, but the hours would differ at each 15° of longitude by steps of one, twenty-four standards encircling the globe. Thus, for example, at 25 minutes past noon of the prime (or rather the zero) meridian, clocks 90° E. would show 25 minutes past 6 p.m. (18h. 25m.); those 90° W., 25 minutes past 6 a.m. (6h. 25m.); and those at 180°, 25 minutes past midnight. The zero meridian adopted by the Prime Meridian Conference is that of Greenwich; and definite time standards based on hourly intervals from this starting-line have been used since 1883 on the railways of North America. That continent is divided into strips 15° in width, in each of which a separate time standard prevails, from the Gulf of Mexico to Hudson Bay. Atlantic time in the eastern provinces of Canada, and in Newfoundland, shows 8 a.m. at Greenwich noon; Eastern time in the Atlantic States of the Union marks 7 a.m. at the same moment; while Central, Mountain, and Pacific time indicate respectively 6, 5, and 4 a.m. The meridians which set the clocks across America are those of 60°, 75°, 90°, 105°, and 120° W.

The conditions in Europe are more complicated than in America. Each small closely-peopled country, with its national Observatory, naturally tends to adopt throughout its particular national time, although even this is still a desideratum in some. In the difficult subdivisions of Imperial Germany especially, the number of independent and unrelated standards was a grievous obstacle to the interpretation of through railway time-tables.

The British Islands, lying at the extreme west of Europe, should logically keep time of the zero meridian, which intersects Greenwich Observatory; while the Russian Empire (in Europe at least) was by its system of central government and State control of railways equally committed to the time of St. Petersburg. But Pulkova Observatory lies two hours east of Greenwich plus one minute and a quarter, and the alteration required is so small that it may be said already to constitute East European time, two hours in advance of Greenwich, or the standard time of West Europe. The meridian of 15° E., running through Norway, Sweden, Germany, Austria, and Italy, corresponds to Central European time, one hour in advance of that of Greenwich, and if national prejudices and local inertia were overcome, the time of Europe would be placed on a very simple footing by its adoption. The railways of Austria-Hungary have used Central European time on this system since October 1, 1891. More than fifty towns in the monarchy have since then regulated their clocks to correspond, Vienna being the only conspicuous exception, where local time is used for local purposes. Servian time-tables have been assimilated to those of Central Europe, and Bulgarian to Eastern Europe; while Turkey, pulled two ways, yields on both sides, following Central European time on the Salonika railway and Eastern European time on the Constantinople line.

In Sweden railway time has been that of Central Europe (15° E.) since 1879, and in South Germany the change to the same standard took place on April 1, 1892, a fact of much greater importance, because a feat very difficult to accomplish. The four standards of Bavaria, Würtemberg, Baden, and Alsace-Lorraine were previously in use concurrently, and the change involved retarding the nominal hours of all trains from 14 minutes in the case of Bavaria to 34 minutes in that of the Reichsland. Luxemburg came into harmony with the rest of Central Europe at the same date, with the loss of 36 minutes.

By a decision of the Federal Council in May last, mean solar time of the 15th meridian will become standard time for the whole German Empire on April 1, 1893, when it exclusively will be employed for railway, telegraph, and all State purposes. Already several places in North Germany have adopted the new time, and it can only be a matter of a few years for the simpler uniform system to acquire a footing for all the purposes of private life.

The number of European time standards is stated by Dr. Busschere [1] to have been 24 on January 1, 1891, and by the end of 1892 it will only be 13. Of these, three are meridional standards, while ten are the times of capitals, viz: Paris, Madrid, Lisbon, Rome, Berne, Bucharest, Athens, Copenhagen, Berlin, and St. Petersburg, but the last, as already mentioned, practically belongs to the former category. It now remains only for France, Spain, and Portugal to adopt Western European time, for Denmark, Switzerland, and Italy to accept Central time, and for Greece and Rumania to join the other Balkan States in using Central or Eastern time, and the change will be complete.

Strangely enough, although foreign writers tacitly assume that the British Islands are at one in their time standard, there exists in the United Kingdom a diversity as illogical as that which formerly reigned in the States of Southern Germany. While Great Britain and the small island groups associated with it keep the time of the initial meridian, now extended to Belgium and Holland on the east, Ireland is regulated by Dublin time. Thus it happens that when the post-office clock in Stornoway (6° 15′ W.) shows noon, that in Donaghadee (5° 30′ W.) only marks 11h. 35m.

As long ago as 1888, Japan adopted for its standard time that of the ninth hour interval from Greenwich (135° E.), so that the clocks which regulate the movements of the Japanese are set nine hours in advance of ours.

India, Australia, and Cape Colony remain independent in their time relations, although so simple a readjustment as is required might form a graceful concession to the spirit of federation without sacrifice of local dignity or utility.

There is no authentic publication known to us which sets forth the time standards actually employed in the chief towns of the world, but fallacious information on the subject is to be found in many atlases and clock-face diagrams. Even so eminently practical a work as "Bradshaw's Railway Guide" contains month after month a map graduated on the margin to show the difference of time between Greenwich and the rest of

---

[1] Bulletin of the Royal Belgian Geographical Society, 1892, No. 2, p. 196. From this paper many of the statements given above have been derived.

England, leaving it to be implied that the local time thus shown is that actually employed, and Kelly's famous directories are disfigured with similar tables.

It is much to be regretted that the system of numbering the hours of the day from 0 to 24 has failed to hold the popular fancy. Despite the big clock-face on Greenwich Observatory, people still know their hours by the old ambiguous titles. Usually there is no room for misunderstanding, but mistakes are sometimes possible. A foreign potentate visiting this country recently was much *fêted* during his short stay, breakfasts, luncheons, and dinners being given in his honour, when a certain judge issued a card of invitation to a "Reception at 10 o'clock," which some of the guests interpreted as a.m., and others as p.m. Missing a foreign Prince through such ambiguity is a trifle compared with missing a train or miscalculating the length of a journey, and yet we know of no English time-table (we have heard of American) in which the simple plan of naming the afternoon hours from 12 to 23 is adopted. The method is occasionally used in the record of scientific observations, and always with advantage.

The present time-standards on the railways of Europe may be summarized as follows:—

(1) *Time of the initial meridian* (Western Europe) 0° (12.0):—Great Britain, Belgium, the Netherlands.

(2) *Time of the first hour interval* (Central Europe), 15° E. (13.0): Sweden, Luxemburg, Germany (Prussia excepted temporarily), Austria-Hungary, Servia, Bulgaria, Western Turkey.

(3) *Time of the second hour interval* (Eastern Europe), 30° E. (14.0): Eastern Turkey, Russia (practically).

Countries conforming to national standards or to no system, with the hour adopted in their capitals at Greenwich noon: Ireland (11.35), France (12.9), Spain (11.46), Portugal (11.23), Switzerland (12.30), Italy (12.50), Rumania (13.44), Greece (13.35).

HUGH ROBERT MILL.

NOTES.

MR. H. T. STAINTON, F.R.S., the well-known entomologist, has been appointed one of the Curators of the Hope Professorship at Oxford, to fill the vacancy caused by the death of Prof. Moseley.

SIGNOR GIUSEPPE FIORELLI is retiring from the general direction of the antiquities of Italy, and his friends and admirers have resolved to mark the occasion by giving expression to their high appreciation of his work as an archæologist. A committee has been appointed by the Accademia dei Lincei to make the necessary preparations. It is proposed that a medal shall be struck in his honour, and that any sum which may remain after this has been done shall be set apart for the encouragement of archæological studies in accordance with Signor Fiorelli's suggestions.

THE second International Congress of Physiology is to be held at Liége on August 28 to 31.

ON Tuesday a conference was held at Lord Brassey's house for the consideration of the best means of establishing a laboratory of marine biology in Jamaica in commemoration of the fourth centenary of the discovery of America. Lord Rosse moved the first resolution, "That an observatory of marine biology in tropical seas is necessary for the development of science." Prof. Ray Lankester seconded the resolution, and in doing so said that nothing could do more to advance our knowledge of biology at the present moment than the work of such a laboratory as that which it was proposed to establish. They wanted a place where the naturalist could work, and above all they wanted an organization, with a permanent official in charge who would gradually accumulate knowledge of the animals and plants which were to be found in the surrounding waters. They wanted in such a laboratory the means of dredging. He hoped they would have a steam vessel, and that the vessel would be large, and the actual building of the laboratory small. He trusted that there would be an adequate private subscription to enable them to build the laboratory, but the carrying on of the work would require an annual income, which he hoped the home Government and the island Government would be prepared to find. The resolution was carried unanimously. Mr. Villiers-Stuart moved, and Mr. Wellesley Bourke (M.L.C., Jamaica) seconded, "That no tropical sea promises so rich a harvest of biological specimens as the great gulf of the West Indies; that Jamaica is the most central and most suitable station for such an observatory, and that its establishment would be a suitable memorial of the fourth centenary of the discovery of the Western Hemisphere." This also was unanimously agreed to.

THE Crystal Palace on Saturday last was specially visited by Lord Kelvin to view the National Electrical Exhibition at present being held in its buildings. This Exhibition, as everyone who has seen it must be aware, is a thoroughly representative one, and besides illustrating the present condition of the application of electricity for practical purposes, carries one back especially in the Post Office exhibit, to the time of its infancy: the historical collection is of considerable importance, and has been well selected. Instruments are there shown, which have five needles on their dials, the presence of which was once necessary to carry on a conversation, the number of words spoken per minute amounting only to single figures. Very interesting old specimens of cables are also shown, together with the part of a telegraph post connected with the pathetic case of a poor woodpecker which, in the endeavour to find the insect that was producing (so he thought) the humming noise in the post, had pecked a large hole in it. In the demonstration room of Messrs. Siemens Brothers, some truly wonderful sights were displayed. The flame produced by exciting an induction-coil by means of an alternating current was produced on a very large scale, and as it issued from the secondary poles, was made to pass through pieces of wood, lumps of salt and slate, the most striking case being its passage through a large piece of plate glass, for which a very strong current was required. Among the many other exhibits, we may mention the demonstrations in cooking by electricity. The bottom of the kettle or saucepan is coated with a specially prepared enamel, into which a fine wire resistance is embedded; by this means, as the wire becomes heated, the temperature of the kettle, and therefore of the water in it, is raised. We may note that the Exhibition closes on Saturday, July 2, so that those who have not already visited it should do so without delay.

A REUTER'S telegram from Vizagapatam, Madras, announces the death of Mr. Narasinga Row, the well-known native astronomer. He died on Saturday last.

THE death of Hermann Burmeister, the well-known German zoologist, at Buenos Aires, is announced. He died on May 1 in his eighty-sixth year. In his early days he was a Professor of Zoology at Halle. During the revolutionary period of 1848 and the following years he associated himself prominently with the Liberals, the result being that in 1850 he had to quit Germany. He travelled for some time in Brazil, and then returned to his native country. He went back to South America in 1856, and not only visited most parts of the Argentine Republic, but crossed the Andes by a way which had never before been taken by a European. After another brief visit to Germany, he finally settled in Buenos Aires in 1861, where he formed the well-known National Museum of Natural Science. Only an accident made it necessary for him to resign his position as Director, and the community, by which his services were highly appreciated, took care that he was properly pensioned. He was buried at the cost of the State, and the President was present at the funeral.

DURING the latter part of last week an area of high pressure lay over the Bay of Biscay and the west of France, and an area of low pressure over Scandinavia and the North Sea, causing moderate north-westerly and westerly winds over these islands. The temperature had continued low, the maxima only exceeding 60° at a few places, chiefly in the southern parts of the kingdom, while the nights were very cold for the time of the year, with ground frosts over the inland parts of England. Thunderstorms occurred in many parts, with heavy showers of rain, and hail in the south-east of England. At the beginning of the present week the low barometer extended gradually over the kingdom, and shallow depressions were travelling from west to east. With this distribution of barometric pressure, the winds were from north and east over Scotland, and chiefly from between north-west and south-west over England and the Channel; subsequently the barometer readings became more uniform, and the winds light and variable. The weather continued very unsettled, although there was some increase of temperature. The report issued by the Meteorological Council for the week ended the 18th instant shows that the mean temperature was below the average for the week in all districts, the deficit ranging from 3° in the Channel Islands to 8° in the Midland and Eastern Counties of England. Rainfall was only slightly above the mean in the east of Scotland.

THE Washington Weather Bureau has just distributed two important meteorological papers prepared by General A. W. Greely, Chief Signal Officer. (1) A series of thirty-seven charts showing the absolute maximum and minimum temperatures in the United States for decades, and for all years combined, compiled from observations taken from 1872 to June 1891. The values, together with the date of occurrence, are printed over the names of the stations on ordinary maps, and show very clearly for each locality the limits within which the temperature may be expected to range. (2) Diurnal fluctuations of atmospheric pressure at twenty-nine selected stations in the United States. The tables give the corrections necessary to reduce the mean pressure at any hour of the day to the true daily mean. The values have been obtained by freehand curves from all the available observations from January 1877 to June 1888. It is found that the fluctuations of the secondary maxima and minima diminish from south to north, especially during the summer months. The daily variation in pressure decreases with increasing latitude, especially in the winter months; in summer the same conditions exist, except that the daily range increases inland from the coast. The principal maximum occurs over the whole of the United States in January, about 9h. 45m. a.m. (local time), except along the New England coast, where it is earlier; as the year advances the hour gradually shifts towards the earlier morning until June, after which a reversal gradually occurs. The delay in the hour of the principal minimum is more marked: it gradually becomes later with increasing longitude; the most decided lagging in the summer minimum is in the neighbourhood of the Great Lakes.

PROF. R. KOBERT gives, in the *Chemiker Zeitung* (1892; 16, No. 39), an account of Williams's frog heart apparatus. The apparatus, as modified by Maki, Perles, and Kobert, consists of an arrangement of glass vessels and india-rubber tubes, whereby a heart taken from a newly-killed frog can be made to maintain an artificial circulation of blood, fresh or injected with any poison the effect of which it is sought to determine. The tubes and vessels are mounted on a stand about 1 foot high. The heart is suspended by a cannula leading into a three-way tube communicating with two vertical glass cylinders fitted with glass valves. Through one of these the heart is supplied with blood, either fresh from a rabbit, calf, or dog, and diluted with 0·75 per cent. salt solution, or poisoned. The other vertical cylinder leads back from the heart to the vessel from which the fresh blood is supplied. To start the action, fresh blood is allowed to enter the heart, which is thereby excited to a contraction, and pumps it back into the reservoir. The height through which it is raised, and the quantity that is raised in a given time, gives the work done, and the number of pulsations, and the volume raised in a given time determines the pulse-volume. The force exerted is measured by a small mercurial manometer, which may be rendered self-registering. To study the action of poisons on the power and vitality of the heart it is only necessary to admit the poisoned blood from the second reservoir. When the pulsation has ceased or diminished, fresh blood may be re-admitted, which in many cases restores the pulsation. We have received a letter on this subject from Count F. Berg, of Livonia, who says Prof. Kobert is of opinion that the apparatus, if it were more generally known, would be of great service for the advancement of science, and would render unnecessary many an otherwise indispensable experiment in vivisection.

WE have received a new planisphere, which is being sold by the *Register* Publishing Company, Ann Arbor, Mich. The rotary disk, on which the constellations are clearly marked, is made of good stiff cardboard, and the days of the year round the edge are neatly printed in white figures on a blue background. The planisphere is arranged for latitudes 38° to 48°, and shows on its disk all the principal stars in each constellation, with their lettering, and in some cases their names; thus, α Boötis = Arcturus, α Lyræ = Vega, &c. By simply turning the disk round until the day of the month comes opposite the time of day, the stars above the horizon at that time can at once be seen. On the back is a table for finding the times of visibility and positions of the planets, while there is also a key to enable one to determine the name of a planet which cannot be recognized. When once used, the handiness of such a planisphere as this will soon make itself apparent; and not only will it be adopted by possessors of telescopes, but it should be in the hands of all those who wish to be able to find and correctly name the various constellations.

INQUIRIES have recently been made by the British Consuls in Japan as to the various native industries that have sprung up for the production of articles which have hitherto been imported into that country from abroad. A summary of the information thus obtained has been prepared by Mr. Gubbins, Secretary of Legation at Tokio, and has been printed in the Foreign Office Miscellaneous Series. Mr. Gubbins says that in the case of some of the industries introduced into Japan, the country is now self-supporting, foreign competition being no longer possible; in others so much has been accomplished as to render it certain that the time is not far off when importation will altogether cease. The future of other industries again—such as that of cotton-spinning—though not so assured, is still hopeful; while even in those branches in which the least results have been obtained she possesses a constant advantage in the great cheapness of labour. Mr. Gubbins thinks that this progress has not been made at the sacrifice of any of the various artistic industries which are more peculiarly her own. While admitting that there is truth in the criticism that would disparage her progress for the reason that it is imitative and not constructive, he holds that the fact that Japan, an Oriental country, has been able to dissociate herself from her sister countries of the East and to profit by Western inventions to the extent that is in evidence augurs well for the years to come.

IN the new number of the *Records of the Australian Museum* (vol. ii., No. 1), Prof. Alfred Newton, F.R.S., has a note which may be of interest to ornithologists in Australia. Having lately occasion to investigate the range of the sanderling (*Calidris arenaria*), he came across a memorandum made in the year

1860 of his having then seen, in the Derby Museum at Liverpool, two specimens of the larger race of this species, one in winter dress and the other in incipient spring plumage, both being marked as females, and as having been obtained at Sandy Cove in New South Wales, April 20, 1844, by the late John Macgillivray. This wandering species does not seem to have been hitherto recorded from Australia. Prof. Newton finds little verification of Temminck's assertion in 1840 ("Man. d'Ornithologie," iv. p. 349), often repeated in one form or another, that the sanderling occurs in the Sunda Islands and New Guinea; or even of a statement made by a recent writer in general terms, that it is a winter visitor to the islands of the Malay Archipelago ("Geographical Distribution of the Charadriidæ, &c.," p. 432). Java seems to be the only one of these islands in which its presence has been determined, and though it was included with a mark of doubt in the lists of the birds of Borneo by Prof. W. Blasius (1882) and Dr. Vorderman 1886) respectively, it has been omitted, and apparently with reason, from that of Mr. Everitt (1889). It is well known to pass along the whole of the west coast of America, and it has been obtained in the Galapagos and the Sandwich Islands, but Prof. Newton knows of no instance of its having been observed in any Polynesian group or within the tropics to the eastward of Java.

IN the same number of the *Records of the Australian Museum* is a valuable paper (with plate), by Mr. Charles Chilton, on a Tubicolous Amphipod from Port Jackson. Among some Australian Crustacea sent to Mr. Chilton as exchanges by the trustees of the Australian Museum was a tube-dwelling Amphipod collected in Port Jackson. There was a plentiful supply both of specimens and of the tubes formed by them, and after a full examination and comparison of them with Mr. Stebbing's description and figures, Mr. Chilton has no doubt that they belong to *Cerapus flindersi*, Stebbing, a species described from a single female specimen taken in Flinder's Passage during the voyage of the *Challenger*. Mr. Stebbing says nothing of the tube in his description, and Mr. Chilton presumes, therefore, that he has not seen it. Mr. Chilton is able to supplement Mr. Stebbing's description in this respect, and to describe the male of the species, and to give the points in which it differs from the female, and also some interesting facts on the changes in form that occur during the growth of the male.

SOME time ago the *Ceylon Observer* gave an account of the killing of a wild boar by a cheetah near Galle. In its issue of May 25 it prints a letter from Mr. Clive Meares, who says that the fortune of war has now gone the other way, a cheetah having been killed by a wild boar. The coolies of Ginniedominie estate, Udagama, on going to work on the morning of May 23, discovered in a tea-field near the jungle signs of a severe struggle having taken place between a cheetah and a wild boar—judging by the marks. On further search the dead body of a cheetah was discovered in the tea, death having evidently been caused by the severe handling it had received from the boar. The brain being very much congested with blood and several teeth marks deeply buried in the neck, there could be no doubt as to the cause of death. On the animal being skinned the wounds were found to be very deep. She weighed 42 pounds, and she was 71 inches long from nose to tip of tail, and 24 inches in height at the shoulders.

MR. A. REA, the Superintendent of the Archæological Survey, Madras, has reported an important discovery he has made of another casket, some relics, and inscriptions in the Buddhist stupa at Bhatuprolu in the Kistna District. In Sewell's *List of Antiquities*, vol. i. p. 7, mention is made of a casket found in the dome of the stupa some years ago. It struck Mr. Rea that as the chief deposit was usually placed near the centre of the foundations, it was probable that another casket might be found. Copies of his report, with inscriptions, have been ordered to be sent to Dr. Hultzsch, the Government Epigraphist; to archæological experts in India, and to various learned Societies.

MINING seems likely to be splendidly represented at the Chicago Exhibition. It is announced that "all of the precious minerals, all of the economic minerals, all of the precious stones, all of the coals, all of the building stones and marbles, all of the clays and sands, all of the salts and pigments, as well as the machinery, implements, and appliances employed in their conversion to the uses of man, will be fully represented." Especial attention will be devoted to the iron industry. The Exhibition will provide ample data as to the location and extent of the greater iron deposits, the analyses of the ores, with all the machinery and devices employed in mining, hoisting, conveying, storing, &c.

PROF. DANIEL G. BRINTON contributes to the new number of the Proceedings of the American Philosophical Society, vol. xxx., No. 137, valuable papers on the Chintantec language of Mexico, the Mazatec language of Mexico and its affinities, and South American native languages. Of the latter languages he says that they are the least known of any in the world.

A VOCABULARY of the Eskimo language has been compiled by M. Ryberg, a Danish official in Greenland. It represents work carried on during fifteen years.

THE publication of the quarterly journal for cryptogamic science, *Grevillea*, will still be continued under the proprietorship of Mr. E. A. L. Batters, and the editorship of Mr. George Massee.

MR. E. D. MARQUAND has published a list of the flowering plants and vascular cryptogams of Guernsey. It includes the remarkable number of 636 flowering plants, 18 ferns, and 9 fern allies. Of these about 130 are not recorded for Guernsey in Prof. Babington's "Primitiæ Floræ Sarniceæ."

THE latest researches of the Finnish expedition to the Kola Peninsula will modify the position of the line which now represents on our maps the northern limits of tree-vegetation in that part of Northern Europe. The northern limit of coniferous forests follows a sinuous line which crosses the peninsula from the north-west to the south-east. But it now appears that birch penetrates much farther north than the coniferous trees, and that birch forests or groves may be considered as constituting a separate outer zone which fringes the former. The northern limits of birch groves are represented by a very broken line, as they penetrate most of the valleys, almost down to the sea-shore; so that the tundras not only occupy but a narrow space along the sea-coast, but they are also broken by the extensions of birch forests down the valleys. As to the tundras which have been shown of late in the interior of the peninsula, and have been marked on Drude's map in Berghaus's atlas, the Finnish explorers remark that the treeless spaces on the Ponoi are not tundras but extensive marshes, the vegetation of which belongs to the forest region. The Arctic or tundra vegetation is thus limited to a narrow and irregular zone along the coast, and to a few elevated points in the interior of the peninsula, like the Khibin tundras, or the Luyavrurt (1120 metres high). The conifer forests, whose northern limit offers much fewer sinuosities than the northern limit of birch-growths, consist of fir and Scotch fir; sometimes the former and sometimes the latter extending up to the northern border of the coniferous zone.

THE British Consul in Hainan, in his last report, says that during the past year he has made two journeys in that island, one to certain prominent hills near Hoihow, known as the "Hummocks," which lie fifteen miles to the west, on the road to Ch'eng-mai, the other a gunboat cruise to Hansui Bay. The people at both these places, and presumably all along the north-west coast, though believing themselves Chinese, speak a language which is not only not Chinese, but has a large percentage of the words exactly similar to Siamese, Shan, Laos, or Muong. The type of the people, too, is decidedly Shan, without the typical Chinese almond eye. At one time (1000 years ago) the Ai-lau or Nan-chau Empire of the Thai race extended from Yun-nan to the sea, and the modern Muongs of Tonquin, like the Shans of the Kwangsi province, the ancestors of both of which tribes belonged to that empire, probably sent colonies over to Hainan; or the Chinese generals may have sent prisoners of war over. It is certain that some at least of the unlettered, but by no means uncivilized, tribes in the central parts of Hainan speak a type of language which is totally different from that spoken by the Shan-speaking tribes of the north-west coast. Yet the Chinese indiscriminately call all the non-Chinese Hainan dialects the Li language. The subject, Mr. Parker says, is one of great interest, well worth the attention of travellers. It was his intention to pursue the inquiry when making a commercial tour of inspection round the island, but his transfer to another post compels him to abandon his scheme.

THE additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. Edward Solomon; two Black Swans (*Cygnus atratus*) from Australia, presented by Lady William Osborne Elphinstone; a Greater Spotted Woodpecker (*Dendrocopus major*), two Common Cormorants (*Phalacrocorax carbo*), British, presented by Sir H. B. Lumsden, K.C.S.I.; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. F. R. Brown; two Common Rheas (*Rhea americana*) from the Argentine Republic, deposited; an Erxleben's Monkey (*Cercopithecus erxlebeni* ♂) from West Africa, a Victoria Crowned Pigeon (*Goura victoriæ* ♀) from the Island of Jobie, two Wonga-Wonga Pigeons (*Leucosarcia picata*) from New South Wales, a Rosy-billed Duck (*Metopiana peposaca* ♀) from South America, twenty Common Teal (*Querquedula crecca*), European, purchased; a Thar (*Capra jemlaica*), two Burrhel Wild Sheep (*Ovis burrhel* ♂ ♀), an Axis Deer (*Cervus axis* ♂), four Temminck's Tragopans (*Ceriornis temmincki*), a Himalayan Monaul (*Lophophorus impeyanus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

COLOURS ON THE SURFACE OF MARS.—During the last opposition of Mars a series of observations was made by Prof. Pickering with the object of determining the general colour of this planet's disk, and that of the various markings distributed over its surface. In a preliminary account of this work which he has contributed to the June number of *Astronomy and Astro-Physics*, we are made acquainted with some of the observed facts, which will be read with keen interest, as we are nearing a time when like observations can be repeated. The instruments used were the 12-inch and 15-inch at Cambridge, and the 13-inch at Arequipa, Peru. With the two former sixty paintings were made, together with sixty-six uncoloured drawings, and with the latter some of the more recent observations were undertaken. The general light from the planet, although usually termed ruddy, was found to lie about midway between that of a candle and electric light of equal brilliancy, being somewhat bluer than the former and redder than the latter.

Great difficulty seems to have been found in matching Mars's colour in the day and night time, the presence or absence of the bluish white light reflected from the atmosphere bringing about a great difference in the colour of the pigments used. The colour finally settled upon may be represented by equal parts of dragon's blood and sienna. The ruddiness, as the limb was approached, gave way to a distinct yellow tint, due perhaps to atmospheric absorption, an effect, as Prof. Pickering remarks, which is quite at variance with the action of our own atmosphere. In addition to these colours grays and greens have been noticed, indeed at times the greens have been more intense than the red. The grey objects were found, when the seeing was very good, to have a slightly yellowish tinge about them, but when viewed by daylight a browner tint more accurately represented their colour.

Numerous observations were made also with the intention of determining the colour of those parts more darkly tinted, and the colour of the canals; but Prof. Pickering only mentions that there were indications of slight colour alterations, reserving his opinion on these points in order not to bias those of other observers, who will be able in the coming opposition to examine this planet's surface from this point of view.

During the months of July and August the planet, excepting for its low altitude, will be most favourably situated for observation, the opposition occurring on August 4, when its distance from the earth will be about 35,000,000 miles.

OBSERVATIONS OF THE MOON.—The *Monthly Notices* (vol. lii., No. 7) contains, besides the observations of the right ascensions and north polar distances of the moon made during the year 1891 at the Radcliffe Observatory, Oxford, a comparison of these results, with the tabular places taken from Hansen's lunar tables. The two suppositions on which these results are compared are, as Mr. Stone says: (1) that the mean times found in the usual way from the sidereal times at mean noon given in the *Nautical Almanac*, were not altered in scale, or affected with any different systematic errors of determination, by the adoption in 1864 of a different ratio of the Julian year of 365¼ "mean solar days" to the mean tropical year; (2) that the "mean times" which accurately correspond to a given "sidereal time of a meridian" were necessarily changed in 1864 by the use of a different ratio of the "Julian year," and therefore of the "mean solar day" to the mean tropical year, to fix the tabular right ascensions of the clock stars at the meridian transits. It is from these tabular right ascensions of the clock stars that the observed right ascensions are deduced by the aid of clocks; and the right ascensions thus found are finally rendered definite by the direct reference to the positions of the sun deduced from the north polar distances and obliquities of the ecliptic.

During the period included in the years 1847 to 1863 the mean annual error in longitude of Hansen's tables amounted to −1″·85, no regular law of increase being indicated. Taking the case of those observations made up to the end of last year, the mean annual error, as shown in the third table, has steadily increased from the year 1863 at an average rate of 0″·75 per annum, the error now amounting to as much as 19″·30. If the corrected argument be used for taking out the mean annual error of Hansen's tables during the same period, this value becomes −1″·49, which differs from −1″·85 (the value for the preceding period) by a quantity which in such a case is very small.

A PLANET BEYOND NEPTUNE?—For some time it has been thought that in all probability our sun is accompanied by one or two other planets which lie outside the orbit of Neptune. The idea gained a considerable footing in many minds after Prof. Forbes's paper, which he read in 1880 before the Royal Society of Edinburgh, his prediction being based on cometary aphelia positions. In order to investigate this question more fully, Mr. Isaac Roberts, having obtained the necessary approximate positions of these hypothetical bodies, undertook to make a search for them, employing the method of long exposure photography. The result of this search he communicates to the May number of the *Monthly Notices*.

The probable position indicated by Prof. Forbes lay between R.A.'s 11h. 24m. and 12h. 12m., with declinations 0° 0′ to 6° 0′ north; and over this region Mr. Roberts took two sets of eighteen plates, each plate covering more than four square degrees, the exposure being of 90 minutes' duration. A close examination of the plates showed that, in Mr. Roberts's words, "no planet of greater brightness than a star of the fifteenth magnitude exists on the sky area herein indicated."

GEOGRAPHICAL NOTES.

THE Royal Geographical Society's *soirée* took place on the 17th inst. at the South Kensington Museum, when the guests were received by the President and Council. The attendance was very great. The attractions of the evening included selections by the Coldstream Guards band, solo and part singing in the lecture theatre, and an exhibition by the dioptric lantern of maps and views, with explanation by Mr. H. J. Mackinder.

SOME interesting particulars as to the present state of the Marshall Islands are published in the *Deutsches Kolonialblatt*. The population is estimated at 15,000 aborigines, and about 100 whites. Cocoa-nuts and copra are the staple exports; pandanus, breadfruit, and arrowroot being cultivated on a small scale. The natural grass is not suitable for pasture, but with the introduction of foreign grass seed, cattle and sheep breeding may become profitable. Taking into consideration the character of the soil and the density of population, the future of the German protectorate in the Marshall Islands is acknowledged not to be very bright, although the authorities hope that it may become of enhanced importance for trade with Germany.

THE *National Geographic Magazine* has just published an account by Dr. Charles Willard Hayes of the expedition through the Yukon district in 1891, conducted by Mr. Schwatka on behalf of a syndicate of American newspapers. Entering by the Yaku inlet, the expedition made its way by canoe, as soon as the ice disappeared, up the Yaku River; thence it crossed the watershed, and continued on Lake Ahklen and the Teslin River to Lewes River, a tributary of the Yukon. A traverse survey was made all the way, and the route laid down in a serviceable manner, though of course without the precision of an actual survey. This district has been several times visited by prospectors, and parts of it mapped by previous explorers; but the expedition opened up, probably for the first time, the unknown region extending from the Yukon to the St. Elias Mountains. Across this blank, usually filled in hypothetically on maps, the expedition surveyed a line of 330 miles, from Selkirk, on the Yukon, to the junction of the Chittenah and Nizzenah rivers. The report gives a clear summary of the topography, drainage, orographic system, and geology of the region traversed.

PRINCE HENRY OF ORLEANS has returned to France after a difficult journey from the Upper Mekong, through the Shan States and Siam, where he reached the coast at Bangkok.

CAPTAIN W. G. STAIRS, whose quiet heroism in Stanley's Emin Relief Expedition was brought prominently before the world two years ago, has fallen a victim to African travel. He was born at Halifax, Nova Scotia, in 1863, and educated at Merchiston Castle School, in Edinburgh, subsequently studying at the Royal Military College, Kingston, Ontario. After his training in Canada he spent some time in New Zealand as a civil engineer; but obtaining a commission in the Royal Engineers, he came to Chatham, and completed his military training. When the Emin Relief Expedition was fitting out in 1887, he volunteered to accompany it; and from the first he impressed Mr. Stanley as a man of exceptional qualities —an opinion strengthened by the strict obedience and absolute loyalty which distinguished him throughout the trying years that followed. As the only member of the advance party (Dr. Parke excepted) who had much interest in scientific matters, Captain Stairs would undoubtedly have made large additions to knowledge had it not been for the imperative exclusiveness of his work as an officer. He was selected for the best piece of geographical exploration attempted during the expedition—the ascent of Mount Ruwenzori. Last year Lieutenant Stairs was promoted to a captaincy, but the fatal attraction of Africa led to his resignation in order to accept command of the Katanga Company's expedition. This Company was formed in Belgium to administer and exploit the south-eastern corner of the Congo Free State, in what is known as Msidi's country. Stairs left Zanzibar last summer, crossed to Lake Tanganyika by the familiar trade route *viâ* Tabora, and reached Mpala on October 31, after a remarkably rapid and easy journey. Thence he traversed Msidi's country in the rainy season, where he suffered much from fever, but succeeded in reaching the Ruo on May 13, and arrived at Vicenti, near the mouth of the Zambesi, on June 3. But at Chinde, just as the expedition had overcome all the difficulties of the way, and only waited for a passage to Zanzibar, Captain Stairs died. This sad event has removed from the list of African travellers one of the bravest, most prudent and modest of young explorers.

THE MICROSCOPE'S CONTRIBUTIONS TO THE EARTH'S PHYSICAL HISTORY.[1]

MEN will have forgotten much when the second half of this nineteenth century is no longer remembered. Whatever may have been its faults, it has no rival in the past history of the world as an epoch of scientific progress. This progress has been largely due to the felicitous co-operation of the mind of the student with the skill of the craftsman in the more perfect construction of instruments of research. By them darkness has been made visible; the opaque, translucent; the unseen, conspicuous; the inert, sensitive; silence, vocal. A thousand methods of experiment, tests of the most delicate nature, have been devised, so that vague conjecture has been replaced by exact knowledge, and hypothesis by demonstration. In such an epoch it may seem a little fanciful to select any one term of years as exceptionally fruitful; but it is remarkable that in the first decade of this half-century, science was enriched by three contributions, each of which has led to consequences of far-reaching import. In 1858 Charles Darwin and Alfred Russel Wallace announced simultaneously the conclusions as to the origin of species at which they had independently arrived, and the well-known book by the former author appeared in the following year. They thus formulated the results of protracted investigations and patient experiments with the simpler appliances of earlier days. They subjected, more strictly than ever before, the facts of nature to an inductive treatment, and thus lent a new impulse to biological science. Their hypothesis gave a definite aim to the researches of students, and kindled an unquenchable flame of intellectual activity. In 1860, Bunsen and Kirchoff announced the results of applying the spectroscope to problems in chemical analysis. By means of this instrument not only have investigations attained a precision hitherto impossible, but also the student, no longer cribbed, cabined, and confined, to the limits of the earth, can question the stars in their courses, and bid nebulæ and comets reveal the secrets of their history. Lastly—though the problem be in a humbler sphere, dealing with neither the immensities of stellar physics nor the mystery of life—Henry Clifton Sorby, in 1856, described the results of microscopic investigations into the structures of minerals and rocks. Strictly speaking, indeed, the method was not wholly novel. So long since as 1827, William Nicol, of Edinburgh, had contrived to make sections of fossil wood sufficiently thin for examination under the microscope; but the device, so far as I know, had not been generally applied, or its wide possibilities apprehended.

You have heard in this place on former occasions of the triumphs of the spectroscope in extra-terrestrial space; of the revelations of the microscope in regard to the least and lowest forms of life; I have ventured to ask your attention to-day to the work of that instrument in a humbler and more limited field —the constitution and history of the earth's crust. My task is beset with difficulties. Did I address myself to experts, these would be but a small portion of my audience; if I speak to the majority, it will be hard to make intelligible a subject bristling with technicalities. Moreover, as this building is so ill-suited for the usual methods of illustration, I have decided to dispense with diagrams or lantern slides, and will try to tell, in the plainest language at my command, the conclusions as to the genesis of rocks and the earlier history of the earth to which the researches of the last few years seem to be tending.

I have excluded from my story investigations which bear upon the biology of the past, though the work of the microscope in this field has not been less fruitful or interesting, because these are more widely known. Moreover, they have not specially engaged my attention, and there is, I believe, an expectation amounting to an unwritten law, that whoever has the honour to occupy my present position should be so far egotistical as to talk of the particular plot, however small it may be, on which he has laboured in the garden of science. So I will crave the indulgence of the few experts present, and the patience of the majority of my audience, while I try to tell the story of microscopical research into the history of the earth's crust.

Twenty years ago, I believe, not half that number of geologists in the British Isles made any real use of the microscope. Now they may be counted by scores, not only in the United Kingdom, but also in every civilized land. Obviously in a science so new, in a research which is extending so rapidly, much diversity of opinion must exist on some theoretical questions. Into the details of controversies it is not my purpose to enter; but I shall content myself with indicating the conclusions to which I have been led in the time which the many inevitable duties of life permitted me to devote to this branch of geology.

---

[1] The Rede Lecture for 1892, delivered before the University of Cambridge, by T. G. Bonney, Sc.D., F.R.S.

Before doing this it may be well to indicate very briefly the mode in which the microscope is applied to the examination of rocks. Commonly it is as follows: slices, cut by the lapidary's wheel from minerals or rocks, are ground down smoothly till they are about one one-thousandth part of an inch thick, and are then mounted on glass. By this means most minerals, including the great majority of the ordinary constituents of rocks, become translucent, if not transparent. They are then examined under a specially-constructed microscope, fitted with Nicol's prisms and other contrivances for optical tests. Occasionally also certain chemical tests can be applied. To what extent an object is magnified depends on the nature of the investigation. A very minute crystal can sometimes be studied, under favourable circumstances, when enlarged to at least 800 diameters; but in ordinary cases, where the chief constituents of a rock and their mutual relations are the object of research, a magnification of from 50 to 100 diameters is commonly the most advantageous. Sands, clays, and incoherent materials can be readily studied by mounting them temporarily or permanently on glass; sometimes, also, good work can be done, and time saved, by crushing up fragments of minerals and of rocks, and by treating the powder thus obtained in the same way. Investigations, which promise to throw light on the problem of the development of minerals, have been recently made by examining the insoluble residues of those rocks which are chiefly composed of carbonates. Solutions of different specific gravities have proved very useful in the determination of the mineral constituents of a rock, which are sorted out by them, as by a strainer, from a sand, mud, or a powdered mass, so that each kind can be studied separately either by microscopical or by chemical analysis.

The subject evidently, in process of time, tends to divide itself into two branches: the one concerned mainly with the characters of the individual constituents of a rock, the other with the wide problem of their mutual relations, or, in other words, with the history of the rock-mass: branches properly denoted by the words *petrography* and *petrology*, though these terms are often confused. The former is more strictly a department of mineralogy; the latter a department of geology. This it is of which I chiefly speak to-day; this it is in which the most marked advances have been recently made.

How great these have been may be more readily appreciated if I mention a few matters, concerning which, even a quarter of a century since, great uncertainty prevailed. Though it was then generally admitted that one great group of rocks, such as clays, sandstones, limestones, &c., were sediments, and that another great group, the rocks called igneous, had solidified in cooling from a fused condition; the origin of a third, and by no means unimportant group, the crystalline schists and gneisses—the metamorphic rocks, as they were commonly called—was considered very doubtful. Many geologists also believed that not a few igneous rocks had been once sediments, like those in the first group, which had been subsequently fused or "digested" by the combined action of heat, water, and pressure. Thus it was supposed that clays and felspathic sandstones could be traced through various stages till they became granite, and rocks of the most diverse chemical composition could be transmuted one into the other. The province of metamorphism was the fairy-land of science; it needed but a touch of the magic wand, and, like Bottom the weaver, a rock was at once "translated." It would be easy, were it worth while, to enumerate instance after instance of these alleged transmutations, every one of which has been proved to be groundless. No doubt, even at the time named, these assertions were questioned by some geologists, but that they could be made so confidently, that they could be inculcated by the official representatives of geology in this country, shows the hopeless confusion into which petrology had fallen.

By means of the microscope also much light has been thrown upon the history even of the better known rocks. The classification of the igneous group has been simplified, and the relations of its several members have been determined. The microscope has dispelled many an illusion, and reduced a chaos to order. In regard to the sedimentary group, it often has determined the true nature of their constituents, and has suggested the sources from which they have been derived or the agents by which they have been transported. Thus, through its tube, we have been enabled, not only to gaze at the most intimate structure and composition of rock-masses, but also to catch glimpses of the earth's physiography in ages long before the coming of mankind.

But in speaking of the services rendered by the microscope, I must not forget a needful caution. If the instrument be employed for petrological rather than petrographical purposes, it must never be divorced from work in the field. No training in the laboratory, however complete, no research in a library, however laborious, can of themselves make a petrologist. No question can be completely mastered, unless it be also studied in the field; nay, even the specimens for examination under the microscope, as a rule, should be collected by the student himself, and the characters and relationships of the rock-masses from which they are detached should be carefully noted. It was said, on no mean authority, some fifty years since, that, in the education of a geologist, travel was the first, the second, and the third requisite. Perhaps the statement, like most epigrams, was somewhat one-sided, but the truth in it has not been diminished by the increased perfection of our instrumental methods. In petrology, the chimæras of the home-keeping student of the laboratory have been, and still are, as hurtful to progress, as the dreams of the peripatetic geologist, whose chief appliances are a stout pair of legs and a hammer.

This, then, was the problem which, some thirty years since, presented itself to geologists who were interested in petrology. Here are two groups of rocks, the sedimentary and the igneous. The origin of these we may be said to know, but as to that third group, which, though not as large, is far from unimportant—what is its history? what are its relations to the other two? The records of its rocks at present are illegible. Is there any hope that success will reward the attempt to decipher them? Time and perseverance have given an answer, and though much is still uncertain, though much remains to be done, some real progress, in my opinion, has been made. As the stones sculptured of old by the hand of man are yielding up their secrets, as the hieroglyphs of Egypt and the cuneiform characters of Assyria are telling the tale of the conquerors whose bones are dust, as the tongues of the children of Heth, and of the black-headed race of Accad, are being learnt anew, so the records of the rocks, wherein no trace of life is found, are being slowly, painfully, but ever more surely deciphered, and knowledge grows from year to year.

To obtain success the problem must be attacked in the following way. As the first step, the two great groups already mentioned, the origin of which is known, must be thoroughly studied. The examples selected must be nearly or quite unaffected by any agent of change, such as heat, water, and pressure. Among the specimens representative of the sediments, the materials must range from fine to coarse—for the grains in the latter serve also as samples of the rocks from which they have been broken, and suggest their own inferences. Among the igneous rocks, types ranging from the most glassy to the most crystalline forms must be examined, in order to ascertain not only the constituent minerals, but also their associations and mutual relations. Suppose this done—suppose a fairly good idea obtained of the characteristic structures and possible variations in either class—we have then to ascertain how far and in what way each representative can be modified by natural agencies. At the outset, probably, it will be found convenient to trace the processes of mineral and even of structural change without any immediate reference to the efficient cause. It soon appears that in the case of minerals, which differ in physical properties, but not in chemical composition, the one species replaces the other; the less stable gradually altering into the more stable form. Thus calcite takes the place of aragonite, hornblende of augite; one mineral may be broken up into a group, as a colloid into crystalloids, or felspar into quartz and white mica; new species may be produced by addition or subtraction of constituents from without, or by exchange from within; the replacement of silicates by carbonates, the conversion of granite into tourmaline-rock, the formation of epidote, chlorites, and serpentine, are a few among the many instances of this kind of change. By tracing the process from one part of a rock to another, numerous facts are collected and relationships ascertained. But during these investigations questions are raised in a student's mind which begin to clamour for an answer. Why does such and such a rock change, now in this way, now in that? So it becomes necessary to correlate our observations, to frame hypotheses, and open out new lines of inquiry.

So far as we know, water, pressure, heat, are the main agents in producing change in rocks, after the latter have been once deposited or solidified. In most cases it is not easy to insulate perfectly the effect of each agent, for probably every rock, which has undergone important changes, has been to some extent affected by all of them. Still many examples can be found, in which the influence of one has predominated greatly over that of the other two. For instance, it is now agreed that the structure of a slate is the result of pressure, though this probably produced a slight rise of temperature, and the rock is not likely to have been perfectly dry. Again, when a clay has been converted into an assemblage of crystalline silicates in the vicinity of an intrusive mass of granite, this is mainly the effect of heat, though the pressure cannot have been inconsiderable, and the presence of water is almost certainly essential.

Thus, in one series of examples, properly selected to illustrate the slaty rocks, we can watch the development of new minerals. We can observe which of these are readily produced and quickly attain to a considerable size, which are more slowly formed, or seem incapable, even if common, of much enlargement. We are thus led by inductive processes to conclusions as to the effects of pressure in the development of minerals in a mass of materials of a particular composition. In another series of rocks which has been affected by the heat of intrusive masses, we can watch the gradual growth of new constituents, as we proceed inward towards the originally heated mass, till we have passed from clay or slate to a crystalline aggregate of minerals, such as quartz, micas, andalusite, staurolite, and garnet. Similar effects may be noted in other kinds of sedimentary rock. Changes also are produced mainly by the action of water, but on this I need not enlarge.

Again, as another line of inquiry, the effects produced on igneous rocks by the same agents must be studied. Here the results which are more or less directly due to the action of water are often highly interesting, but as these are only indirectly connected with the main subject of this lecture, I content myself with a passing reference. With igneous rocks the effects of heat seem generally less important than with sedimentary; probably because the mineral constituents of the former are usually in a more stable condition than those of the latter, so that these also need only be mentioned; but the effects of pressure in some cases, especially with the more coarsely crystalline igneous rocks, are highly interesting and significant.

In a region such as the Scotch Highlands or the European Alps the rocks, in the process of mountain-making, have been obviously subjected, perhaps at more than one epoch, to tremendous pressures. The effect of these appears to have been sometimes a direct, sometimes a shearing fracture; that is to say, a mineral or rock, in the one case, has been crushed, as in a press, in the other, during the process of powdering it has been dragged or trailed out, with a movement somewhat similar to that of a viscous substance. As an example, let us take the effects produced in a granite by crushing. The grains of quartz are broken up; the crystals of felspar are first cracked and then reduced to powder; the mica flakes are bent, riven, and tattered. By pressure also the solvent power of water, already present in the rock, is increased; by the crushing its access to every fragment and its subsequent percolation are facilitated. Thus the black mica is often altered in various ways; the felspar dust is changed into white mica and chalcedonic quartz; the constituents are reduced in size and tend to assume a roughly parallel order; the mineral character and structure have been alike changed; a massive rock has been replaced by a foliated one; a coarse granite by a fine-grained quartzose or micaceous schist. This change can be demonstrated at every stage; it suggests that many foliated rocks—many gneisses and crystalline schists—may be igneous rocks of which both the mineral character and the structure have been modified by pressure.

We may presently see how far this inference can be justifiably extended, but, as a first step, the effect of pressure on one of the more basic igneous rocks must be considered. Let us take as an example a coarse-grained variety of the rock, which is familiar to us as basalt. It consists of a felspar, different from that of granite, of augite, of some iron oxide, and perhaps of olivine. In studying this rock we are confronted by greater difficulties, for, of the two dominant minerals, the felspar is rather less stable than that which occurs in granite, and the augite passes readily into hornblende. Thus, when the latter change occurs we are at first unable to determine whether it is due to pressure or to some other agent. Some petrologists, I believe, would not hesitate to appeal to the presence of hornblende in a rock such as we are considering as a proof that it had been modified by pressure. With this opinion I cannot agree. On examination of the numerous instances in which we are convinced that the hornblende is not an original constituent but has replaced augite, we notice that the former mineral is not constant in its characters. It may be granular in form; it may assume its usual crystalline shape; it may be more or less bladed or needle-like. Have these differences, we ask, any significance? In order to answer the question, specimens of hornblendic rocks must be sought in regions which obviously have been subjected to tremendous pressure, as is testified by the fact that every other rock has been more or less crushed or rolled out; others must be obtained from regions where the associated masses exhibit no signs of extraordinary disturbance, even though they may be more brittle than the subject of our study. In the former case the change may be reasonably attributed to pressure, in the latter it must be due to some other cause. Are hornblendic rocks from the one region similar in structure to those from the other? By no means. Where no evidence can be offered in favour of pressure, there the hornblende either retains wholly or almost wholly the outline of the mineral which it has replaced, or else assumes its normal prismatic form; but where an appeal to pressure seems justifiable, we find that the hornblende appears as unusually elongated prisms, blades, or even needles, and the structures of the rock as a whole can be readily recognized by a practised eye. The evidence for the latter statement is yet unpublished, but it will, I hope, appear before long.

So our investigations have led us thus far: that, in sedimentary rocks, in the presence of water, certain changes are mainly produced by heat, and certain by pressure. In the latter case, however, the new minerals, though very numerous individually, are generally minute; the longest diameter being seldom so much as one-hundredth of an inch. Even where this rule is broken, it is only by minerals which are proved by other experiments to be so readily developed that their presence on a large scale has no real significance. The rule holds also to some extent in the case of crystalline schists produced by the crushing of crystalline rocks, markedly in the case of those derived from granites and rocks of similar composition, but less conspicuously in those which were originally augitic or hornblendic. Though even here, where the decreased size of the minerals is less uniformly marked, new and distinctive structures are assumed.

I have spoken only of two or three common types of rocks, but it would be easy, did time permit, to support the principles enumerated, by quoting from a great variety of examples. There are, I believe, few, if any, important kinds of rock which have not been examined, and it appears to me demonstrated that, while pressure is a most important agent of change,[1] while many schists may be regarded as resulting from it, a considerable group remains, which are separated from the others by a very wide chasm, and this can only be jumped by deserting reason and trusting hypothesis.

In this last group of rocks (supposing no disturbances produced by subsequent pressure, for which, however, we can generally make allowance) the constituent minerals are commonly fairly large—say from about one-fiftieth of an inch upwards in diameter. Very many of these rocks, when studied in the field, exhibit every indication of a sedimentary origin. Though as a rule no original constituent grain can be certainly determined, though they are now crystalline, yet their general structure and association are inexplicable on any other supposition. They bear some resemblance to the sediments which have been altered by contact metamorphism, though they present different characters. These, moreover, remain invariable through considerable thicknesses of rock and over wide areas. The alteration is regional, not local, so that such rocks cannot be regarded as cases of simple contact metamorphism, even though heat may be suspected of having been an important agent in producing the change. But to another large series, including many of the rocks commonly called gneisses, the sedimentary origin is less easily attributed. Not a few of these in mineral composition correspond with granites, and sedimentary rock thus constituted, though not unknown, is rare. The minerals commonly exhibit a parallel or foliated and not seldom even a banded arrangement; in the latter case the layers of different mineral composition in their mutual relations and associations imitate with remarkable success the structure of a banded sedimentary rock. Even a dozen years since little doubt was entertained that this group also had a detrital origin. Occasionally, however, its members, when studied in the field, exhibited characteristics which were difficult to explain on any such hypothesis, and presented resemblances in habit to certain crystalline igneous rocks, from which, however, they were proved to differ in their microscopic structures.

---

[1] It is probable that some changes of importance are produced in rocks by long-continued and repeated pressures, which are insufficient to give rise to crushing; but these I have passed by, because, as it seems to me, further evidence is needed before we can diagnose, with any certainty, the results of this particular disturbing cause.

In rocks which have crystallized from a state of fusion some of the mineral constituents usually exhibit their proper crystalline outlines; but in these others the same minerals had no definite shape, and were simply granular. Of this structure two types were observable: in the one the grains were elongated, in the other they were roundish in outline but slightly wavy or lobed. The former type was commonly found in the more distinctly banded varieties; the latter in the more massive and faintly foliated kinds which in hand-specimens were not readily distinguished from true granite.

As in rocks, no less than in living beings, diversities of structures are nature's record of a difference in history, it became a question whether these peculiarities were significant of origin or of environment. By prolonged observations the following results were established:—(1) That crystalline rocks, which could be proved, by their relation to others, to be truly igneous, sometimes exhibited banded structures. (2) That these structures, in certain cases, could not be attributed to any subsequent pressures or crushings, for no sign of them could be found in neighbouring rocks, which, from their composition and nature, ought to have yielded more readily. (3) That a faint foliation or banding, especially in the case of granitic rocks, could be sometimes detected in irruptive veins, in which cases the aforesaid granular structure was detected on microscopic examination. (4) That cases were occasionally found where a light-coloured granite had broken into a dark hornblendic rock, and the fragments of the latter had been gradually softened, elongated, and even drawn out into bands, together with the intruder, till they perfectly simulated, as already mentioned, a stratified mass. (5) That in certain of these cases, where a rock, exceptionally rich in hornblende, had been partially fused by a pale-coloured granite, a banded black-mica gneiss had been produced, indistinguishable, macroscopically and microscopically, from those which have been already mentioned.

It follows from these observations that the great group of crystalline rocks, which are connoted comprehensively as schists and gneisses, includes rocks which may have originated in one of three different ways:—(1) Some have once been molten, but have become solid under rather exceptional circumstances, probably having lost heat slowly, and having continued to move very gradually during the process of consolidation. (2) Others have been produced by the thorough alteration of sedimentary materials, in which a high temperature has been maintained for a long time, in the presence of water and under considerable pressure. (3) Others, again, have been the result of great pressure, which has acted on rocks already crystalline, and has produced mineral changes, sometimes to the complete obliteration of the original structure. The second and third of these groups are truly metamorphic rocks, to the first the term, strictly speaking, is not applicable.

As a rule, it is not difficult to distinguish between these three groups, and in all probability the ambiguities which still remain will be solved by patient and persevering work. Cases, no doubt, will occur on which no inference can be founded; cases where, from one cause or another, nature's record has become illegible. But to this disappointment the scholar and the archæologist has to submit equally with the geologist. Negative evidence of this kind has no disturbing power; any amount of it is outweighed by a single scrap of clear and positive testimony. It is generally a waste of time to puzzle over bad specimens; they are much more likely to produce a perplexed agnosticism than a rational faith; for a creed has its place in science no less than in theology.

I have mentioned one mode in which materials rather markedly different in mineral character may be, in a certain sense, interstratified and to some extent blended, but should add that recent researches render it highly probable that there are other modes in which mineral or chemical constituents may be differentiated in a magma which was once homogeneous. To discuss these would carry us into questions of crystallogenesis, which have no direct bearing on my present subject, though in these also the microscope has rendered the most valuable services by suggesting inferences and by testing theoretical conclusions; questions upon which so much light has been thrown by the researches of Guthrie, Lagorio, Sorby, and others; but I may refer in passing to the law established by Soret, that by a change of temperature a homogeneous solution may be rendered heterogeneous; since any compounds by which it is nearly saturated tend to accumulate in the colder parts. Gravitation also, when certain minerals are crystallizine from a magma, may cause them to rise or to sink, and in this way also heterogeneity may be produced. So when the mass of mingled fluids and solids is constrained to move, a streaked or banded structure may be the result produced; as in a process familiar to the glass-blower.

But when the geologist has learnt from the microscope to recognize differences of structure in crystalline rocks, and to appreciate their significance, he finds that a wider problem is presented to his mind, provided he has not been led by the fascinations of laboratory studies to despise or neglect work in the field. Granted that one group of rocks, covered by the term metamorphic, has undergone great changes since its members were first deposited or solidified, can these be connected with any phase in the earth's history? Have they any chronological significance? Even twenty years since few geologists would have hesitated to reply:—"None whatever: a rock may have undergone metamorphism at any epoch in the past. Muds and sands of Eocene, Jurassic, Carboniferous, Silurian, of any geological age, have been converted into crystalline schists. Proofs of some part of this assertion can be found even within the limits of the British Isles; it can be completely established within those of Europe." But during the last few years this hypothesis has been on its trial; witness after witness in its favour has been, so to say, brought into court, and has broken down under cross-examination. I can assert this without hesitation, for I have some personal knowledge of every notable instance in Europe which has been quoted in the debate. Microscopic study, combined with field work, has invariably discovered that some very important link in the supposed chain of proof is wanting, and has demonstrated without exception that these crystalline schists are very old; much more ancient always than any neighbouring rock to which a date can be assigned, if not older than the first rocks in which any trace of life has been found. It has been also demonstrated that sedimentary masses, after they have been buried deep beneath superimposed strata and exposed to great pressure, have emerged comparatively unchanged. Such rocks are most valuable as illustrations of the effects of dynamical and other agencies; but they are sufficiently distinct from the crystalline schists to indicate that the environment in the one case must have differed greatly from that in the other. The results of contact metamorphism prove that heat is an important agent of change; but as these also present their own marked differences, they fail to afford a complete solution of the problem.

Moreover, among ordinary sedimentary rocks, we cannot fail to notice that, as a rule, the older the rock the greater the amount of mineral change in its constituents. A good illustration of this is afforded by the Huronian system of North America, the rocks of which are rather older than the Cambrian of this country. Some of them, while still retaining distinct indications of a sedimentary origin, have become partially crystalline, and supply examples of a transition from a normal sediment to a true crystalline schist. Even the older Palæozoic rocks almost invariably exhibit considerable mineral changes, though with them it is only on a microscopic scale. Hence, taking account of all these results, we seem to be forced to the conclusion that the environment necessary for changing an ordinary sediment into a crystalline schist existed generally only in the earliest ages, and but very rarely and locally, if ever, since Palæozoic time began.

Further, in regard to those peculiar structures which, as already stated once led geologists to consider certain rocks, really of igneous origin, as metamorphosed sediments; they also appear to have been much more frequently produced in the earliest ages. They are common in association with the ordinary crystalline schists; they are found, so far as I know, rarely, if ever, with little altered sediments. The microscopic study of the coarser stratified rocks—grits, sandstones, &c.—lends some support to this view, by showing that, as we go back in time, a larger proportion of their materials, *cæteris paribus*, has been derived from crystalline rocks, and that even the fragments, obviously of sedimentary origin, exhibit signs of some mineral change; that is to say, the mudstones and sandstones in the later grits are apt to be represented in the earlier by phyllites and quartzites.

So the results of microscopic study, in alliance with, not divorced from, work in the field, lead us to the conclusion that in the early ages of this globe's history conditions generally prevailed which became gradually, perhaps even rapidly, rare and local; or, in other words, that in geology the uniformitarian doctrine must not be stated in terms wholly unlimited, though, since this was first enunciated by Lyell, nothing has been discovered to shake our faith in its general truth, or to resuscitate the catastrophic hypothesis which it replaced. But geologists are forbidden by students of physics to regard the universe as a "self-winding clock." The latter affirm, and the former frankly admit, that this globe through long ages has been losing heat by radiation; that there was a time when the temperature of its surface far exceeded that of molten iron: a temperature which now would be reached only at a depth of many miles. If this be so, the conditions under which rocks were formed on the surface of the globe in early days must have been very different from those which subsequently prevailed. Suppose, for example, this surface to have been just white-hot—namely, at a temperature much below that at which most, if not all lavas, consolidate. In that case the ocean would be vapour, and the weight of the atmosphere would be augmented by that of a shell of water of the area of the globe, and two miles in thickness; or, in other words, the atmospheric pressure would be about 350 times its present amount. If so, even a lava-flow would consolidate under a pressure equivalent to that of some 4000 feet of average rock. But after the surface temperature had become low enough to permit the seas to be gathered together, and the atmospheric pressure had become normal; after rain and rivers, winds and waves, had commenced their work; after sediments, other than the "dust and ashes" of volcanoes, had begun to accumulate; still these at a short distance below the surface would find a very different environment from that which now exists. It has been proved by Lord Kelvin that at the end of about one twenty-fifth portion of the whole time which has elapsed since the first solidification of the earth's crust, the underground temperature must have risen at nearly six times its present rate. To reach a zone, the general temperature of which is 212° F., it would now be necessary to descend, as a general rule, at least 8200 feet, and probably rather more. But in those early days the crust would have been at this temperature at a depth of about 1600 feet, and at 10,000 feet it would have risen to 1050° F., instead of 250° F., which now would be exceptionally high. To this depth many rocks, both in Palæozoic and later ages, have been buried, and they have emerged practically unchanged. Hence it follows that the latter temperature is comparatively ineffective; the former, however, could not fail to facilitate mineral changes and the development of coarsely crystalline structures.

These changes, these structures, have been produced in sedimentary rocks in the immediate neighbourhood of a large mass of intrusive igneous rock, such as a coarse granite. To what temperature the former have been raised cannot be ascertained. Suppose, however, it were 1500° F., which probably is not a very erroneous estimate, this temperature, at the epoch mentioned, would be found at a depth of 15,000 feet. It is now, probably, at least 15 miles beneath the surface. In other words, the zone at which marked mineral changes could be readily produced, quickly sank, and has long since reached a depth practically unattainable. The subterranean laboratory still exists, but the way to it was virtually closed at a comparatively early period in the earth's history.

Another effect of this rapid downward increase of temperature must not be forgotten. When it amounted to 1° F. for every 10 feet of descent, a temperature of 2000° F. would have been reached at a depth of not quite four miles. This would be rather above the melting-point of many rocks, if they were at the surface; so that, even under the pressure, they would be either very near it or imperfectly solid. If the thickness of the crust were only about four miles, flexures would be readily produced, and the effects of tidal stresses would be considerable; but even if the earth had become solid as a whole, there would have been large masses of rock, comparatively near to the surface, in an unstable condition, and thus liable locally to slow deformations, displacements, fluxional movements, and intrusion into other masses already at a high temperature, with the result of partial melting down and mutual reactions. Disturbances such as these, slow, but constantly recurring, would produce structures imitative of stratification. It is a remarkable coincidence, to say the least, that these structures are characteristic of Archæan rocks, and are extremely rare, if ever present, in those of later date.

But some geologists are so rigidly uniformitarian as to shrink from admitting that any portion of the earth's original crust can possibly be preserved. "Take time enough," they say, "and the changes can be made." But will time alone suffice for every kind of change? How long will it be before gunpowder explodes at blood-heat? But passing over this obvious difficulty, we may ask: Is there time enough? So geologists once thought, as fancy travelled back over endless æons. But they are checked by the physicist: "earth and sun alike," he affirms, "are masses subject to the laws of radiation; these countless millions of years of which you dream will bring you to a period when not only the earth, but also the whole solar system, was nebulous. All the history of your planet, physical as well as vital, so far as it can be covered by your records, must be compressed into a very moderate number of millions of years, for we have to consider the possibilities not only of a cooling earth, but also of a cooling sun." If this be so, and it seems difficult to dispute the decision; if we are forbidden to look back along "the corridors of time" till they vanish in the perspective of infinite distances, it becomes more and more probable that the whole volume of the earth's history is within our reach, and that its opening chapters will some day be deciphered.

The progress which has been made since the microscope was pressed into the service of geology augurs well for the future, if we work in a spirit of scepticism and a spirit of hope. Of scepticism, lest we trust too much either in ourselves or in even the princes of science; for experience proves that the seductive charms of phantom hypothesis may lead all alike astray from the narrow path of truth into the morasses of error. Of hope, for experience also proves that by patient labour and cautious induction many an illusion has been dispelled and many a discovery been made. Our eyes must soon grow dim, our hands become nerveless, but other workers will be found to take warning from our mistakes and to profit by our toil. The veil which shrouds the face of Nature may be never wholly withdrawn, but its fringe has been already raised; even in our own generation so much has been accomplished that the hope may be indulged of at last learning something of the history of these earliest ages, when the earth had but lately ceased to glow, and when the mystery of life began.

THE LADIES' CONVERSAZIONE OF THE ROYAL SOCIETY.

THE Ladies' *Conversazione* of the Royal Society took place on the evening of June 15 last, and in every way was a distinct success, the attendance being the greatest on record, and all the available space both for the guests and exhibits being fully occupied. The exhibits, although they included a few that were shown at the last *soirée*, were for the most part new, and the following is a brief summary of the most noticeable of them:—

Dr. H. Hicks, F.R.S., showed the remains of a mammoth found in Endsleigh Street, in March last, at a depth of only 22 feet. The bones were of enormous proportions, and in their proximity was discovered a tusk which was estimated to have been 12 feet in length.

A series of enlarged transparent sections of the fossil plants of the Coal-measures were exhibited by Prof. W. C. Williamson, F.R.S.

Most interesting were the water-colour drawings of Greek temples, &c., by Mr. F. C. Penrose, which illustrated his current investigations on the astronomical orientation of ancient Greek temples. The drawings included those of the Propylæa, the Temple of the Wingless Victory, Parthenon, west and east fronts of the Parthenon, north portico of the Erechtheum, east portico of the Theseum, and the Temple of Jupiter Olympius.

Mr. W. M. Flinders Petrie showed some excellent water-colour drawings of the pavement which he has recently discovered in the Palace of Chuenaten at Tell el-Amarna (1400 B.C.) during his recent excavations. This pavement is quite unique in Egypt, and is especially valuable owing to the marvellous treatment of the plants depicted.

The water-colour sketches exhibited by Prof. F. W. Oliver (for the Scientific Committee of the Royal Horticultural Society) illustrated some typical examples of the damage done to plants by London fog. The injuries shown, he said, were exceedingly prevalent amongst cultivated hot-house plants in the London district during this kind of weather, and extended to a considerable distance from the metropolis, cases occurring as far as Cooper's Hill and Dorking. The sulphurous acid of the fog seemed, in many cases, to have acted directly on the living substance of the foliage and leaves, producing these lesions, while in others there seemed to have been evidence of an accumulative action of the deposits of sulphuric acid.

Mr. W. Crookes, F.R.S., who at the last *soirée* repeated some of Tesla's wonderful experiments, exhibited a novelty in the form of burning nitrogen. He employed an electric current of 65 volts and 15 amperes, alternating 130 times a second, passing it through the primary of a large induction coil. From each of the secondary poles, flames became visible, and met at the centre, being composed mainly of burning nitrogen; when the terminals were separated, so that the flames could not strike across but were in consequence extinguished, it was found that by putting them nearer together a lighted taper was sufficient to re-ignite them. The temperature of the flame exceeds slightly that of a good blowpipe, and a spectroscopic examination of the flame itself shows simply a faint and continuous spectrum. Mr. Crookes pointed out that such a method of exciting an induction coil was first employed by Mr. Spottiswoode in 1880, but "it is not known, however, that any chemical explanation of the flame has before now been published."

Mr. A. A. C. Swinton showed some very interesting photographs of electrical discharges that had been obtained by simply causing the discharges to take place across the surfaces of prepared sensitive dry plates, and consequently without the intervention of any lens. The distinctive character of the figures by the two kinds of discharges were very noticeable, so also was the evidence of their oscillatory nature.

Other electrical exhibits were:—

An ingenious device for disconnecting the supplier of electricity if a dangerous voltage happened to be established in a house, and a leakage indicator for high tension currents, both exhibited by Messrs. Drake and Gorham.

Electrical discharges over prepared surfaces, by Mr. J. Wimshurst, showing that over imperfectly conducting surfaces of large area branch-like forms of flashes are produced, and with a great difference of potential sparks of seven feet in length can be attained.

High-tension electrical apparatus, by Mr. L. Pyke, for working a considerable number of vacuum tubes from one generating source, the tubes in this case being each connected with terminally connected inductors, themselves counterpoised against two external conductors connected to the terminals of the transformer.

The Director of the Royal Gardens, Kew, exhibited a specimen of a double cocoa-nut (*Lodoicea seychellarum*), with illustrations showing its germination. This palm is tall and fan-leaved, and peculiar to two of the Seychelles Islands; its fruit weighing from 25 to 30 pounds. At the germination of the seed, "the embryo is gradually pushed out of the seed by the growth of the seed-leaf (cotyledon). One end of this remains attached to the seed, and conveys to the embryo the nutriment derived from the gradual absorption of the endosperm." Three of the drawings and a model had an additional interest in that they were made by the late Major-General Gordon.

Mr. Romanes's exhibits of living rats and rabbits attracted much attention, and would perhaps have attracted slightly more if any of the former animals had by chance got astray. They were illustrative of some of the results of experimental breeding with reference to theories of heredity. The examples clearly showed that the male and female elements did not *always* so blend together that the offspring presented characters more or less intermediate between those of the parents, but that the progeny sometimes took wholly after the father or wholly after the mother.

Another animal exhibit consisted in a living specimen of a remarkable non-venomous South African snake (*Dasypeltis scabra*), from the Zoological Society of London. This animal lives solely on birds' eggs. Each egg is swallowed whole, and by a muscular contraction of the gullet, its contents flow into the stomach, while the shell is rejected by the mouth in the form of a pellet.

Among the other exhibits we may mention the systematic and simple construction of the dark absorption bands A, B, and *a* in the solar spectrum, after Mr. Higgs's photographs, by Prof. A. S. Herschel, F.R.S.; the photographs of stellar spectra, including Nova Aurigæ, Arcturus, &c., by Mr. Norman Lockyer, F.R.S.; the photographs of leguminous plants for the determination of the fixation of free nitrogen, by Sir J. B. Lawes, Bart, F.R.S., and Dr. J. H. Gilbert, F.R.S.; and an ingenious instrument for measuring the thermal expansion of very minute solid bodies up to high temperatures, and tracing the volume charge of the silicates up to and over the interval of plasticity, by Mr. J. Joly, F.R.S.

The exhibit in the Archives Room, by the Postmaster-General, was during the whole evening thoroughly appreciated, the Telephone Company's installation being the means by which the guests were able to listen to the music of Salammbo from the grand opera at Paris. Previous to the switching on of the opera, conversation was carried on with some of the officials at the Paris end, and the accuracy with which the peculiarities of the various voices were transmitted was little short of marvellous.

The lantern demonstrations also attracted considerable attention. Mr. Saville Kent and Mr. C. V. Boys, F.R.S., as at the previous *soirée*, both showed their photographic slides, those of the former dealing with coral reefs, &c., and those of the latter with flying bullets. Mr. Norman Lockyer exhibited some photographs taken both at home and foreign Observatories, illustrative of the application of photography in astro-physical researches. The slides included some beautiful photographs of stellar spectra and solar prominences, from the Paris Observatory; of the moon and Jupiter, taken with the large Lick instrument; of the nebulosity surrounding η Argûs, photographed by Dr. Gill, F.R.S.; of the great February sun-spot, taken in India and forwarded to the Solar Physics Committee; and of the spectra of Nova Aurigæ and Arcturus, taken at Kensington. The most striking slide of all was that of the great nebula of Orion, taken by Dr. Common, F.R.S., with his five-foot reflector at Ealing. The apparent brilliancy of the stars, and the wonderful tracery in the nebulous parts, appealed to the eye not so much as an image of a slide on a screen, but as a direct view of this beautiful object through the great telescope itself. The slides shown by Mr. E. B. Poulton, F.R.S., were illustrative of the methods by which the originally opaque wings of certain butterflies and moths had become transparent and usually scaleless; numerous stages in the generation of scales were also shown.

THE FOURTH CENTENARY OF COLUMBUS.

DURING the present year great celebrations will take place in Spain, Italy, and America, in memory of Columbus and his first adventurous voyage of 1492. Although no public commemoration is arranged for in this country, the Royal Geographical Society, fully conscious of the momentous nature of that first voyage, and of the enormous expansion of geographical science which has resulted from it, set apart last Monday evening for a special Columbus meeting. The usual exhibition of maps and pictures included a number of early charts of great beauty, and a fine photograph of a contemporary portrait of Columbus, recently made known by Mr. Markham. The paper of the evening, read by Mr. Clements Markham, C.B., F.R.S., was occupied with an account of recent discoveries with regard to Columbus, and the correction of many erroneous ideas widely entertained until now. As a critical summary of perhaps one of the most difficult branches of research—that into the actual life of a popular hero enhaloed with centuries of tradition—this paper is of great value. An abstract of it, and of the appendices on other fifteenth century explorers, is given below.

Much new light has been thrown upon the birth and early life of Columbus of late years by the careful examination of monastic and notarial records at Genoa and Savona.

There is no doubt as to the birthplace of Columbus. His father was a wool-weaver of Genoa, whose house was in the Vico Dritto di Ponticelli, which leads from the gate of San

Andrea to the church of S. Stefano. It was battered down during the bombardment of Genoa in the time of Louis XIV., was rebuilt with two additional stories, and is now the property of the city of Genoa.

Here Columbus was born, the date of his birth being fixed by three statements of his own, and by a justifiable inference from the notarial records. He said that he went to sea at the age of fourteen, and that when he came to Spain in 1485 he had led a sailor's life for twenty-three years. He was, therefore, born in 1447. The authorities who assign 1436 as the year of his birth rely exclusively on the guess of a Spanish priest, Dr. Bernaldez, Cura of Palacios, who made the great discoverer's acquaintance towards the end of his career.

The notarial records, combined with incidental statements of Columbus himself, also tell us that he was brought up, with his brothers and sister, in the Vico Dritto at Genoa; that he worked at his father's trade and became a "lanerio," or wool-weaver; that he moved with his father and mother to Savona in 1472; and that the last document connecting Cristofero Colombo with Italy is dated on August 7, 1473. But in spite of his regular business as a weaver, he first went to sea in 1461, at the age of fourteen, and he continued to make frequent voyages in the Mediterranean and the Archipelago—certainly as far as Chios.

When Columbus submitted his proposition for an Atlantic voyage to the Spanish sovereigns, they referred it to a committee, presided over by Father Talavera, which sat at Cordova, and condemned it as impracticable. It is generally supposed that the proposals of the Genoese were subsequently submitted to an assembly of learned persons at the University of Salamanca, and again condemned. The truth was quite different. Columbus was gifted with a charming manner, simple eloquence, and great powers of clear exposition. It was an intellectual treat to hear him recount his experiences, and the arguments for his scheme. Among those who first took an interest in his conversation, and then became a sincere and zealous friend, was the Prior of the great Dominican Convent of San Estevan, and Professor of Theology at Salamanca, who shrewdly foresaw that the most effectual way of befriending Columbus would be by affording ample opportunities of discussing the questions he raised. For this object there could be no better place than the University of Salamanca, where numerous learned persons were assembled, and where the Court was to pass the winter. The good Prior lodged his guest in a country farm belonging to the Dominicans, called Valcuebo, a few miles outside Salamanca. Hither the Dominican monks came to converse on the great deductions he had drawn from the study of scientific books, and from his vast experience, discussing the reconciliation of his views with orthodox theology. Later, in the winter, Columbus came into the city and held conferences with men of learning, at which numerous courtiers were present. These assembages for discussion—sometimes in the quiet shades of Valcuebo, sometimes in the great hall of the convent—excited much interest among the students and at Court. The result was, that the illustrious Genoese secured many powerful friends at Court, who turned the scale in his favour when the crucial time arrived. Such is the slight basis on which the story of the official decision of the Salamanca University against Columbus rests.

Captain Duro, of the Spanish Navy, has investigated all questions relating to the ships of the Columbian period and their equipment with great care; and the learning he has brought to bear on the subject has produced very interesting results. The two small caravels provided for the voyage of Columbus by the town of Palos were only partially decked. The *Pinta* was strongly built, and was originally lateen-rigged on all three masts, and she was the fastest sailer in the expedition; but she was only 50 tons burden, with a complement of eighteen men. The *Niña*, so-called after the Niño family of Palos, who owned her, was still smaller, being only 40 tons. The third vessel was much larger, and did not belong to Palos. She was called a "nao," or ship, and was of about 100 tons burden, completely decked, with a high poop and forecastle. Her length has been variously estimated. Two of her masts had square sails, the mizen being lateen-rigged. The crew of the ship *Santa Maria* numbered fifty-two men all told, including the admiral.

Friday, August 3, 1492, when the three little vessels sailed over the bar of Saltes, was a memorable day in the world's history. It had been prepared for by many years of study and labour, by long years of disappointment and anxiety, rewarded at length by success. The proof was to be made at last. To the incidents of that famous voyage nothing can be added. But we may at least settle the long-disputed question of the landfall of Columbus. It is certainly an important one, but it is by no means a case for the learning and erudition of Navarretes, Humboldts, and Varnhagens. It is a sailor's question. If the materials from the journal were placed in the hands of any midshipman in Her Majesty's Navy, he would put his finger on the true landfall within half an hour. When sailors such as Admiral Becher, of the Hydrographic Office, and Lieutenant Murdoch, of the United States Navy, took the matter in hand, they did so. Our lamented associate, Mr. R. H. Major, read a paper on this interesting subject on May 8, 1871, in which he proved conclusively by two lines of argument that Watling Island was the Guanahani or San Salvador of Columbus.

The spot where Columbus first landed in the New World is the eastern end of the south side of Watling Island. This has been established by the arguments of Major, and by the calculations of Murdoch, beyond all controversy. The evidence is overwhelming. Watling Island answers to every requirement and every test, whether based on the admiral's description of the island itself, on the courses and distances thence to Cuba, or on the evidence of early maps. We have thus reached a final and satisfactory conclusion, and we can look back on that momentous event in the world's history with the certainty that we know the exact spot on which it occurred—on which Columbus touched the land when he sprang from his boat with the standard waving over his head.

The discoveries of Columbus, during his first voyage, as recorded in his journal, included part of the north coast of Cuba, and the whole of the north coast of Española. The journal shows the care with which the navigation was conducted, how observations for latitude were taken, how the coasts were laid down—every promontory and bay receiving a name—and with what diligence each new feature of the land and its inhabitants was examined and recorded. The genius of Columbus would not have been of the same service to mankind if it had not been combined with great capacity for taking trouble, and with habits of order and accuracy.

Columbus regularly observed for latitude with Martin Behaim's astrolabe or the earlier quadrant, when the weather rendered it possible, and he occasionally attempted to find the longitude by observing eclipses of the moon with the aid of tables calculated by old Regiomontanus, whose declination tables also enabled the admiral to work out his meridian altitudes. But the explorer's main reliance was on the skill and care with which he calculated his dead reckoning, watching every sign offered by sea and sky by day and night, allowing for currents, for leeway, for every cause that could affect the movement of his ship, noting with infinite pains the bearings and the variation of his compass, and constantly recording all phenomena on his card and in his journal. Columbus was the true father of what we call proper pilotage.

On his return his spirit of investigation led him to try the possibility of making a passage in the teeth of the trade wind. It was a long voyage, and his people were reduced to the last extremity, even threatening to eat the Indians who were on board. One night, to the surprise of all the company, the admiral gave the order to shorten sail. Next morning, at dawn, Cape St. Vincent was in sight. This is a most remarkable proof of the care with which his reckoning must have been kept, and of his consummate skill as a navigator.

In criticizing the Cantino map showing Cortoreal's coastlines, Mr. Markham showed that absurd mistakes had been made, not by the voyager or his pilots, but by the cartographer, and subsequent commentators. Vespucci's description of his "first voyage" in 1797, was subjected to very thorough criticism, and shown, in spite of the arguments of authors who have tried to support the veracity of that ingenious romancer, to have been a pure fabrication. Little or no credit could be given to Vespucci in any case, as he was forty-eight years old on first going to sea, and in those days apprenticeship from boyhood was indispensable for a knowledge of seamanship.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Science Examiners have issued the following Class Lists:—

Chemistry.—First Class: C. L. Fort (New), R. E. Hughes

(Jesus), G. Ingham (Merton), A. L. Ormerod (New). Second Class: D. Berridge (Wadham), P. Henderson (Queen's), A. E. Richardson (Wadham), F. R. L. Wilson (Keble). Third Class: C. J. M. Parkinson (Jesus), H. Wynne-Finch (New). Fourth Class: S. Wellby (Trinity).

Physiology.—First Class: P. S. Hichens (Magdalen), H. H. G. Knapp (non-Coll.), A. C. Latham (Balliol), E. Mallam (Magdalen), W. Ramsden (Keble). Second Class: G. J. Conford (Christ Church), E. Stainer (Magdalen). Third Class: S. B. Billups (non-Coll.). Fourth Class: J. S. Clouston (Magdalen).

Physics.—First Class: S. A. F. White (Wadham). Second Class: G. M. Grace (Jesus). Third Class: none. Fourth Class: F. W. Bown (University), J. C. W. Herschel (Christ Church).

Morphology.—First Class: R. W. T. Günther (Magdalen).

Botany.—Second Class: O. V. Darbishire (Balliol).

Women:—Louisa Woodcock is placed in the Second Class, Morphology.

University Extension.—In a Convocation held on Tuesday the following persons were declared on a scrutiny to be duly elected as delegates, under the provisions of the statute Of the delegates for the extension of teaching beyond the limits of the University:—H. J. Mackinder, M.A., Student of Christ Church; W. W. Fisher, M.A., Corpus Christi College, Aldrichian Demonstrator of Chemistry; J. F. Bright, D.D., Master of University College; A. Sidgwick, M.A., Fellow of Corpus Christi College; J. Wells, M.A., Fellow of Wadham College; and the Rev. W. Lock, M.A., Fellow of Magdalen College.

The Encænia.—In a Convocation holden in the Sheldonian Theatre on Wednesday, June 22, the degree of D.C.L. (*honoris causâ*) was conferred upon the following persons:—

His Excellency, William Henry Waddington, Ambassador Extraordinary and Minister Plenipotentiary from the French Republic at the Court of St. James, Honorary Fellow of Trinity College, Cambridge, Hon. LL.D.

His Highness the Thakore of Gondal.

The Very Rev. Henry George Liddell, D.D., late Dean of Christ Church.

Edward Caird, M.A., Professor of Moral Philosophy in the University of Glasgow, formerly Fellow of Merton.

W. M. Flinders Petrie.

The Rev. John Gwynn, D.D., Regius Professor of Divinity in the University of Dublin.

Daniel John Cunningham, M.D., Professor of Anatomy and Chirurgery in the University of Dublin.

Edward Dowden, LL.D., Erasmus Smith's Professor of Oratory in the University of Dublin.

The Rev. John P. Mahaffy, D.D., Professor of Ancient History in the University of Dublin.

Benjamin Williamson, M.A., Sc.D., Fellow of Trinity College, Dublin.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 2.—"On Current Curves." By Major R. L. Hippisley, R.E. Communicated by Major MacMahon, F.R.S.

(1) Starting with the equations

$$i = \frac{E}{R}\left(1 - e^{-\frac{Rt}{L}}\right)$$

and

$$i = \frac{E}{\sqrt{(R^2 + p^2L^2)}}\sin(pt - \theta),$$

which represent the curves of currents in circuits *without* iron cores, according as the impressed E.M.F. is constant or varying as sin pt, we can determine the curves according to which the current rises and falls in circuits *with* iron cores, both for a constant impressed E.M.F. and for a sinusoidal E.M.F.

(2) In the first case, with constant applied E.M.F., we can determine by Lagrange's formula of interpolation the equation to the (B, H) curve of the particular core under consideration. This will be of the form

$$B = a_0 + a_1H + a_2H^2 + \ldots + a_nH^n,$$

where n is one less than the number of observed simultaneous values of B and H from which the equation is calculated. Substituting in the equation

$$E - \frac{dB}{dt} = Ri,$$

we get, after integration,

$$t = b_0 \log\frac{E}{E - Ri} - b_1 i - b_2 i^2 - \&c., \text{ to } n + 1 \text{ terms},$$

b_0, b_1, b_2, &c., being numerical. The paper gives b_0, b_1, b_2, &c., in terms of the constants of the circuit, &c.

The corresponding equation when the E.M.F. is removed and the current is dying away is

$$t = c_0 \log\frac{E}{Ri} - c_1 i - c_2 i^2 - \&c. + \text{a constant}.$$

From these two equations the curves can be plotted.

(3) This method is not applicable to the case in which the impressed E.M.F. is sinusoidal, on account of difficulties of integration. But both cases can be treated in another way:—Take a series of points on the (B, H) curve of the iron core, such that the chords joining them practically coincide with the curve itself. Let B_κ, H_κ, and $B_{\kappa+1}$, $H_{\kappa+1}$, be the co-ordinates of two consecutive points. The equation to the curve between these points is approximately

$$B = m_{\kappa+1}H + \text{constant},$$

where

$$m_{\kappa+1} = \frac{B_{\kappa+1} - B_\kappa}{H_{\kappa+1} - H_\kappa}.$$

Substituting in the equation

$$E - \frac{dB}{dt} = Ri,$$

we get, after integration,

$$t_{\kappa+1} = t_\kappa + \frac{m_{\kappa+1}L}{R}\log\frac{E - Ri_\kappa}{E - Ri_{\kappa+1}},$$

which is true to a very close approximation for any simultaneous values of t and i between the above limits. From this equation, by determining the various values of m, and remembering that t_0 and i_0 are both zero, we can determine in succession the times at which the current has the known values 0, $\frac{H_1}{L}$, $\frac{H_2}{L}$, . . . &c., and the current curve can be plotted.

On making $E = 0$ in the original differential equation, and observing the proper limits, we get

$$t_{n+1} = t_n + \frac{m_{n+1}L}{R}\log\frac{H_n}{H_{n+1}}$$

as the equation to the curve representing the dying away of the current when the E.M.F. is withdrawn; m_n, m_{n+1} being determined from the descending (B, H) curve.

(4) When the impressed E.M.F. is sinusoidal, we substitute for dB/dt in the equation

$$E\sin pt - \frac{dB}{dt} = Ri,$$

having determined the various values of dB/dt, as in the foregoing.

As by the present method the value of m changes *abruptly* from m_κ to $m_{\kappa+1}$, we must employ the *general* solution of the above, which for the interval t_κ, $t_{\kappa+1}$, is

$$i = \frac{E}{\sqrt{(R^2 + m_{\kappa+1}{}^2p^2L^2}}\sin(pt - \theta_{\kappa+1}) + A_{\kappa+1}e^{-Rt/m_{\kappa+1}L},$$

in order that the current at the commencement of the interval t_κ, $t_{\kappa+1}$, may have the same value which it had at the end of the interval $t_{\kappa-1}t_\kappa$. The complementary function

$$A_{\kappa+1}e^{-Rt/m_{\kappa+1}L},$$

enables us to insure this condition; for, by taking the constant $A_{\kappa+1}$ of such a value that the above equation is satisfied when $i = i_\kappa$ and $t = t_\kappa$, there is no abrupt change in the current. The complementary function, in fact, represents the gradual dying away of whatever excess or defect of current there would be in the circuit when m changes.

This equation is true for all values of i between i_κ and $i_{\kappa+1}$; and, therefore, enables us to find the time, $t_{\kappa+1}$, at which the current attains the known value $H_{\kappa+1}/L$.

By changing κ into $\kappa + 1$, we obtain similarly the time $t_{\kappa+2}$ at which the current has the value $H_{\kappa+2}/L$, and so on.

Thus the determination of $t_{\kappa+1}$ is made to depend upon t_κ, and in order to make a start we must assume that the value of i is known for some definite value of t. It is not of much consequence what assumption, within reason, is made, as, though the calculated curves will vary with the assumption made, they will all eventually merge into the true periodic current curve at some point which will be exhibited when the *first* evanescence of $Ae^{-Rt/mL}$ takes place.

As this complementary function is a continually decreasing quantity, it becomes negligible when it is allowed time enough. This opportunity is afforded when the straighter portions of the (B, H) curve are reached.

In the paper are given diagrams showing the plotted curves of current calculated from the above equations, together with tables of calculated values.

"The Conditions of the Formation and Decomposition of Nitrous Acid." By V. H. Veley.

The main points of this inquiry may briefly be summarized as follows:—

(1) The formation of the impurity of nitrogen peroxide in nitric acid, imparting to it the well-known yellow tint, takes place in the case of the more concentrated acid, even at a temperature of 30°, and of the less concentrated acids at from 100°–150°, even when the acid is not unduly exposed to sunlight.

(2) The reaction between nitric oxide and nitric acid may be regarded as reversible, thus:—

$$2NO + HNO_3 + H_2O \rightleftarrows 3HNO_2,$$

provided that the acid be sufficiently dilute, and the temperature sufficiently low. Under these conditions equilibrium is established between the masses of nitric acids when the ratio of the former to the latter is, roughly speaking, as 9 : 1. The actual ratio varies slightly on the one side or the other, according to the conditions of the experiments. With more concentrated acids and at higher temperatures the chemical changes taking place are more complicated, and the decomposition of the acid more profound.

(3) The decomposition of solutions containing both nitric and nitrous acids is also investigated; the rate of the change is shown to be proportional to the mass of the nitrous acid undergoing change. The curve representing the amount of chemical decomposition in terms of the mass present is shown to be hyperbolic, and illustrative of the law

$$\text{(I.)}\ \frac{dC}{dT} = -\frac{C^2}{M}.$$

This holds good, whatever be the method employed for the production of the nitrous-nitric acid solution.

The observed values for C or the concentration of the nitrous acid are concordant with those calculated according to the above differential equation within the limits of experimental error.

The rate is dependent upon the ratio of the masses of the nitrous and nitric acid, being the more rapid, the greater the proportion of the former to that of the latter.

In the particular case of the liquid prepared from nitric oxide and nitric acid, wherein the reproduction of solutions of similar concentration presents less difficulty, it is shown that as the temperature increases in arithmetical the rate of change increases in geometrical proportion, in accordance with the equation

$$\text{(II.)}\ v_t = v_{t_1} k^{(t-t_1)},$$

the value for k being 0·158.

Finally, though the nitrous-nitric acid solutions behave in a similar manner as regards the diminution of the mass of the nitrous acid, yet, in other respects, such as evolution of gases and the action upon metals, they are dissimilar.

"On the Method of Examination of Photographic Objectives at the Kew Observatory." By Major L. Darwin. Communicated by Captain Abney, R.E., F.R.S.

The paper describes the method of examination of photographic objectives which has been adopted at the Kew Observatory, chiefly on the recommendation of the author. In selecting and devising the different tests, Major Darwin acted in co-operation with Mr. Whipple, the Superintendent of the Observatory, and was aided by consultations with Captain Abney.

The object of the examination is to enable any one, on the payment of a small fee, to obtain an authoritative statement or certificate as to the quality of an objective for ordinary purposes.

An example is first given of a "Certificate of Examination," such as would be obtained from Kew, and then the different tests are discussed in detail. The following are the different items in the Certificate of Examination, or the various tests to which the objective is subjected:—

(1) to (4) None of this information forms part of the result of the testing.

(5) *Number of External Reflecting Surfaces.*

(6) *Centering in Mount.*

(7) *Visible Defects, such as Veins, Feathers, &c.*

(8) *Flare Spot.*

(9) *Effective Aperture of Stops*, which is given for each one supplied with the objective. In recording the results, it is proposed that the system of numbering recommended by the International Photographic Congress of Paris of 1889 should be adopted.

(10) *Angle of Cone of Illumination, &c.*

(11) *Principal Focal Length.*—This is found by revolving the camera through a known angle, and measuring the movement of the image of a distant object on the ground glass; with the Testing Camera it is so arranged that an angular movement can be given with great ease and accuracy, and that the angle is such that half the focal length is directly read off on a scale on the ground glass. The observation is made when the image is at a point some 14 degrees from the axis of the objective, and the effect of distortion and curvature of the field is discussed; it is proved that the focal length thus obtained, even though it may not be identical with the principal focal length as measured on the axis, is nevertheless what the photographer in reality wants to ascertain.

(12) *Curvature of the Field.*

(13) *Distortion.*—This test depends in principle on ascertaining the sagitta or deflection in the image of a straight line along one side of the plate. In the discussion it is shown that to give the total distortion near the edge of the plate would not answer practical requirements, and that the proposed method of examination does give the most useful information that can be supplied.

(14) *Definition.*—This is found by ascertaining what is the thinnest black line the image of which is just visible when seen against a bright background. It is shown that this is the best method that could be devised of measuring the defining power of an objective, and that it is not open to serious objections on theoretical grounds.

(15) *Achromatism.*—In the Certificate is recorded under this heading the difference of focus between an object when seen in white light and the same when seen in blue or red light.

(16) *Astigmatism.*—This test is performed by measuring the distance between the focal lines at a position equivalent to the corner of the plate, and by calculating from the result thus obtained the approximate diameter of the disk of diffusion due to astigmatism.

(17) *Illumination of the Field.*—The method of examination, which is due to Captain Abney, is described.

"On Certain Ternary Alloys. Part VI. Alloys containing Aluminium, together with Lead (or Bismuth) and Tin (or Silver)." By C. R. Alder Wright, D.Sc., F.R.S., Lecturer on Chemistry and Physics in St. Mary's Hospital Medical School.

The experiments described in this paper are a continuation of the previous researches on the miscibility of molten metals under such conditions that whereas two of the metals, A and B, will not mix together in all proportions, the third, C, is miscible in all proportions with either A or B severally. The alloys now investigated are those where A is lead (or bismuth); B, aluminium; and C, tin (or silver). They show considerable analogy with, and resemblance to, those previously described containing the same metals as A and C respectively, but zinc instead of aluminium as B; but certain differences are noticeable: thus the substitution of aluminium for zinc invariably *raises the critical curve*, causing it to lie *outside* its former position, this being observed whether the heavy immiscible metal, A, be lead or bismuth, and whether the solvent metal, C, be tin or silver. On the other hand, the substitution of bismuth for lead always *depresses the critical curve*, causing it to lie *inside* its former position; this being equally observed whether the lighter immiscible metal, B, be zinc or aluminium, and whether the solvent metal, C, be tin or silver. In the case of the metals bismuth-zinc-silver and lead-zinc-silver, peculiar bulges (inwards and outwards) were noticed in certain parts of the critical curve, due to the formation of definite atomic compounds, $AgZn_5$ and Ag_4Zn_5; no corresponding indications are observed when aluminium replaces zinc in these mixtures, whence apparently similar atomic combinations of silver and aluminium are not formed. On the other hand, lead-zinc-tin and lead-aluminium-tin alloys correspond sharply with each other in that they are the only alloys yet examined where the direction of slope of the tie lines is not the same throughout; in each case the lower ties slope to the left (lead side), and the upper ones to the right (zinc side); the point where the angle of slope of the lower ties is a maximum corresponds in each case with a ratio between lead and tin in the heavier alloys formed approximating pretty closely to that indicated by the formula Pb_3Sn, suggesting that the sloping of the lower ties is due to the formation of this definite atomic compound. The upper ties in each case exhibit a tendency to converge towards a point on the right-hand side of the curve, approximately where the ratios of zinc to tin and aluminium to tin respectively are those indicated by the formulæ Zn_4Sn, and Al_4Sn; suggesting the existence of these definite compounds.

In the course of the experiments, it is shown incidentally that bismuth and aluminium are practically immiscible when molten: at about 900° C. bismuth dissolves less than 0·1 per cent. of aluminium, whilst aluminium dissolves about 2·0 per cent. of bismuth. The binary alloys of bismuth and aluminium stated by previous observers to exist are simply more or less intimate intermixtures of the two metallic solutions.

"On the Theory of Electrodynamics as affected by the nature of the Mechanical Stresses in Excited Dielectrics." By J. Larmor.

The various theories of electrodynamics are examined from the standpoint of their ability to explain the experimental facts as to pressures in liquid dielectrics which have been made out by Quincke and other experimenters.

The principal conclusions are as follow:—

(1) It follows from the experimental results that the stress in an excited fluid dielectric between two condenser plates consists, at any rate to a first approximation, of a tension along the lines of force and an equal pressure in all directions at right angles to them, superposed upon such stress as would exist in a vacuum with the same value of the electric force.

(2) It follows from experiments that the numerical value of these additional equal tensions and pressures is, at any rate to a first approximation, $(K - 1)F^2/8\pi$, where F is the electric force, and K the inductive capacity.

(3) Such a distribution of equal tension and pressure is necessarily the result of a uniform volume distribution of energy in the dielectric, irrespective of what theory is adopted as to its mode of excitation.

(4) If we consider the mode of excitation to be a *quasi*-magnetic polarization of its molecules, the numerical magnitude of these stresses should be

$$\frac{K - 1}{8\pi}F^2\left(1 + \lambda\frac{K - 1}{4\pi}\right),$$

where λ is a coefficient which depends on the molecular discreteness of the medium, and is probably not very different from the value $\frac{4}{3}\pi$. A discrete polarization of the molecules does not account for the stress, so far as this coefficient is concerned.

(5) The stress which would exist in a vacuum dielectric is certainly due in part to a volume distribution of energy, as is shown by the propagation of electric waves across a vacuum. There is thus no reason left for assuming any part of it to be due to a distribution of energy at its two surfaces, acting directly on each other at a distance. There is therefore ground for assuming a purely volume distribution of energy in a vacuous space, leading to a tension $(1/8\pi)F^2$ along the lines of force, and a pressure $(1/8\pi)F^2$ at right angles to them.

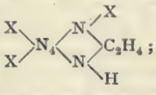
(6) The *quasi*-magnetic polarization theory rests on the notion of a dielectric excited by a surface charge on the plates, and therefore involves a surface-distribution of energy, unless in the extreme case when the absolute value of K is very great; in that case a slight surface-charge produces a great polarization effect, and in the limit the polarization may be taken as self-excited. Thus the absence of a surface-distribution of energy leads to Maxwell's displacement-theory, in which all electric currents are circuital, and the equations of electrodynamics are therefore ascertained.

(7) It appears that even this limiting polarization theory must be replaced, on account of the stress-formula in (4), by some dynamical theory of displacement of a more continuous character.

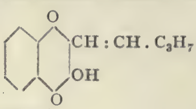
"The Hippocampus." By Dr. Alex. Hill.

Observations upon the brains of various aquatic mammals which show that, when the sense of smell is completely absent, as judged by the total suppression of the olfactory bulb and nerves, the essential constituent of the "hippocampus," the fascia dentata, is absent also. Amongst other mammals the fascia dentata varies in development as the olfactory bulb.

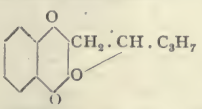
Chemical Society, June 2.—Dr. W. H. Perkin, F.R.S. Vice-President, in the chair.—The following papers were read:—Ethylene derivatives of diazoamido-compounds, by R. Meldola and F. W. Streatfeild. The authors find that ethylene diazoamides result from the action of ethylene dibromide and caustic alkali on diazoamides dissolved in alcohol. The products thus obtained have the general formula—



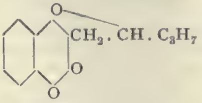
mixed ethylene-diazoamides can also be obtained. These compounds are very stable, and are decomposed by prolonged contact with concentrated hydrochloric acid at ordinary temperatures.—The action of light on silver chloride, by H. B. Baker. The small loss in weight which silver chloride undergoes on exposure to light has led the author to investigate whether oxygen is absorbed at the same time that chlorine is evolved, Robert Hunt having long ago stated that such an absorption does occur. Silver chloride was placed in a bulb connected with a long tube standing over caustic potash solution; the atmosphere consisted of air or oxygen. On exposing this apparatus to light, the liquid rose in the tube, showing that oxygen had been absorbed. The proportion in which the elements silver, chlorine, and oxygen were contained in the darkened substance was then determined. The results agree approximately with the formula Ag_2ClO. The experimental difficulties in the way of an exact determination of the composition of the darkened product are very great, owing to the fact that the dark substance is mixed with an enormous quantity of unchanged silver chloride. The product of exposure to light never contains more than 0·1 gram of the dark-coloured substance per 50 grams of unaltered silver chloride. Another cause of inaccuracy complicates the result if the analyses be not made immediately after exposure; the darkened substance turns white again if left in the dark, probably owing to the formation of another oxychloride. The thoroughly dried darkened substance yields water on reduction in pure hydrogen, and also evolves oxygen on treatment with pure chlorine. The results of determinations of the constituents of the darkened product made by various analytical methods agree as well as could be expected. Silver chloride does not darken when exposed to light in absence of oxygen. No darkening was observed in a vacuum, in carbon dioxide, or in carefully purified carbon tetrachloride. It is, however, difficult to eliminate traces of alcohol, carbon disulphide, &c., from carbon tetrachloride, and the darkening caused by these impurities has hitherto been confounded with that caused by oxygen. Darkened silver chloride dissolves completely in boiling potassium chloride solution, and the solution so obtained contains caustic potash. The production of this free alkali seems to prove conclusively that oxygen is present in the darkened substance in the combined state.—The estimation of slag in wrought iron, by A. E. Barrows and T. Turner. Cast iron comparatively rich in non-metallic elements is known to afford a greater yield of puddled bar than do purer samples of iron. The loss on reheating and rolling into finished iron is, however, also greater. This difference has been attributed to intermingled slag. The authors prepared four samples of iron, viz. best bar, best sheet from the same bar, common bar, and common sheet from the same. Pig iron of known composition was used; the yield of common puddled bar was 6·5 per cent. greater than that of the other, but the loss on reheating was also 1·5 per cent. greater, leaving a balance of 5 per cent. in favour of the common iron. The results of analyses show that the silicon is equally, and very slightly, reduced in each case, whilst the phosphorus was much reduced in common iron, and but scarcely affected in best. This does not favour the view that much more slag is removed in one case than in the other. The authors conclude that for practical purposes the weight of slag in best and common iron may be taken as identical, and that on reheating and rolling each loses about the same weight of slag. The additional loss noticed on reheating impure iron is due chiefly to the elimination of phosphorus, probably in the form of ferrous phosphate. On attempting to estimate the slag by combustion in chlorine, a method already employed for cast iron, it was found that the slag was readily attacked by the gas at a very low red heat. An examination of the behaviour of a number of iron ores and slags showed that action occurs according to the equation $3FeO = Fe_2O_3 + Fe$; the free iron subliming as ferric chloride.—Corydaline, ii., by J. J. Dobbie and A. Lauder. Analyses of salts of corydaline are given in support of the formula $C_{22}H_{29}NO_4$, originally proposed by the authors for this alkaloid. The alkaloid employed by them is identical with that extracted by Adermann from the roots of *Corydalis cava*. Corydaline yields four molecular proportions of methyl iodide on treatment with concentrated hydriodic acid; the hydriodide of a new base $C_{18}H_{21}NO_4,HI$ is also obtained. The conclusion that corydaline contains four methoxy-groups is confirmed by the inability of the authors to obtain any definite reaction with phenylhydrazine or phosphorus pentachloride.—The action of bromine on allylthiocarbimide, by A. E. Dixon. Allylthiocarbimide readily combines with bromine, yielding dibromopropylthiocarbimide as an oily liquid which decomposes on distillation under ordinary pressures. This compound does not afford dibromopropylphenylthiourea when treated with aniline, but the two substances react with elimination of hydrogen bromide and formation of a compound of the formula $C_{10}H_{11}BrN_2S$, probably *n*-phenylbromotrimethylene-ψ-thiourea.—The hydrolytic functions of yeast, Part i., by J. O'Sullivan. It is generally stated, on the authority of Berthelot, that the water in which yeast has been washed possesses, like yeast itself, the power of hydrolyzing cane sugar, and that the active substance can be precipitated from the solution by means of alcohol. The author shows, however, that healthy yeast yields none of its invertase to water in which it is washed. When such yeast is placed in contact with sugar, hydrolysis is effected solely under the immediate influence of the plasma of the cell, no invertase leaving the cell while hydrolysis is taking place. A detailed account is given of experiments carried out under various conditions, which show that water which had been in contact with highly active yeast for various times had no hydrolytic power, although on the addition of a mere trace of invertase, it at once became active. The author therefore concludes that the resolution of cane sugar under the influence of yeast is entirely due to zymic hydrolysis.—The constitution of lapachic acid (lapachol) and its derivatives, by S. C. Hooker. Lapachic "acid" is found in a crystalline state in the grain of a number of South American woods, and derives its name from the lapach tree, which is plentiful in the Argentine Republic. On treatment with sulphuric acid, lapachol is converted into an isomeride generally known as lapachone. The author proposes to term this latter substance β-lapachone, it being a derivative of β-naphthaquinone. When lapachol is treated with concentrated hydrochloric acid, α-lapachone, a derivative of α-naphthaquinone is obtained. The author assigns the following constitutional formulæ to these three isomerides—



Lapachol.



α-Lapachone.



β-Lapachone.

It is shown that Paterno's isolapachone in reality contains less hydrogen than the lapachones, and is doubtless a β-naphthaquinone-propyl-furfuran.

Linnean Society, June 2.—Prof. Stewart, President, in the chair.—The Vice-Presidents for the year having been nominated by the President, a vote of thanks to the officers of the Society was proposed by Mr. Thomas Christy, seconded by Mr. C. J. Breese, and carried.—Mr. H. Bernard exhibited specimens and made remarks on the probably poisonous nature of the hairs and claws of an Arachnid (*Galeodes*).—On behalf of Capt. Douglas Phillott there was exhibited a curious case of malformation in the beak of an Indian parrakeet, *Palæornis torquatus*. The upper mandible was so abnormally decurved as almost to penetrate between the rami of the lower mandible, and although the bird was in good condition at the time it was shot by Capt. Phillott at Dera Ismail Khan, Punjab, in March last, it was evident that had it not been killed then, death must have soon ensued from a severance of the trachea by the sharp extremity of the prolonged mandible.—Mr. D. Morris exhibited, and made some very instructive remarks on, plants yielding Sisal hemp in the Bahamas and Yucatan, and pointed out their distribution and mode of growth. He also exhibited and described the preparation of a gut silk from Formosa and Kiungchow.—Mr. Scott Elliott gave a brief account of a journey he had recently made to the west coast of Africa, and described the character of the vegetation of the particular region explored, and the plants collected by him.—Mr. Jenner Weir exhibited and made remarks on a species of Psyche.—On behalf of Mr. Ernest Floyer, a paper was read by the Secretary on the disappearance of certain desert plants in Egypt through the agency of the camel.—Mr. F. Perry Coste gave an abstract of a paper on the chemistry of the colours in insects, chiefly Lepidoptera. The paper was criticized by Prof. Meldola, who was unable to accept the views expressed, the results of the experiments made being, in his opinion, inconclusive.—The meeting was brought to a close by the exhibition of an excellent oxyhydrogen lantern, recently presented to the Society by Dr. R. C. A. Prior, when Dr. R. B. Sharpe exhibited a number of coloured slides of birds designed to illustrate the interesting subject of mimicry and protective coloration.

Geological Society, June 8.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—The Tertiary microzoic formations of Trinidad, West Indies, by R. J. Lechmere Guppy. (Communicated by Dr. H. Woodward, F.R.S.) After giving an account of the general geology of the island, and noticing previous memoirs devoted to that geology, the author describes in detail the characters of the Naparima Beds, to which he assigns an Eocene and Miocene age. He considers that the Nariva Marls are not inferior to but above the Naparima Eocene Marls, and are actually of Miocene date. Details are given of the composition and characters of the "argiline," the foraminiferal marls occasionally containing gypsum, and the diatomaceous and radiolarian deposits of Naparima. The Pointapier section is then described, and its Cretaceous beds considered, reasons being given for inferring that there was no break between the Cretaceous and Eocene rocks of the Parian area. Detailed lists of the foraminiferal faunas of the marls are given, with notes. The author observes that the Eocene molluscan fauna of Trinidad shows no near alliances with other known faunas, thus differing from the well-known Miocene fauna of Haiti, Jamaica, Cuba, Trinidad, and other localities. Only one mollusk is common to the Eocene and Miocene of the West Indies. The shallow-water Foraminifera are found in both Eocene and Miocene, whilst the deep-water Foraminifera are nearly all of existing species. It would appear that during the Cretaceous and Eocene periods a sea of variable depth (up to 1000 fathoms) occupied the region now containing the microzoic rocks of Trinidad, whilst a mountain-range (which may be termed the Parian range) extended continuously from the north of Trinidad to the littoral Cordillera of Venezuela, forming the southern boundary of the Caribbean continent, and possessing no large streams to transport mechanical sediment into the Cretaceo-Eocene sea which opened eastward into the Atlantic. An appendix by Mr. J. W. Gregory deals with the microscopic structure of the rocks. The reading of this paper was followed by a discussion, in which the President, Dr. H. Woodward, Mr. J. W. Gregory, Mr. Vaughan Jennings, and Dr. Hinde took part.—The Bagshot Beds of Bagshot Heath (a rejoinder), by the Rev. A. Irving. — Notes on the geology of the Nile Valley, by E. A. Johnson Pasha and H. Droop Richmond. (Communicated by Norman Tate.) The rocks on either side of the Nile are chiefly Eocene (and Cretaceous?) from Cairo to Esneh; south of this is sandstone, which the authors believe to be Carboniferous, and to yield possible indications of coal, reaching to near Assouan, where it meets the granite and basalt of that region; a few miles south the sandstone begins again and continues to Wady Halfa, broken only by granite dykes. The granite is intrusive into and alters the sandstone, whilst the latter reposes upon the basalt and in some cases was deposited against upstanding basaltic masses. Unmistakable lavas occur near the Nile east of Minieh and west of Assiout. A description of some remarkable faults is given, and various minerals are noticed as occurring in the sedimentary rocks and the bed of an ancient river.

Mathematical Society, June 9.—Prof. Greenhill, F.R.S., President, in the chair.—Prof. Henrici exhibited a model of movable hyperboloids of one sheet. In 1873 he gave a student at University College the problem to construct a model of a hyperboloid of one sheet by fixing three sticks anyhow, placing others so as to cut these, and tying them together wherever they met. He told the student that the system would soon become rigid, but was surprised to find that this was not the case. It was easy to see the reason of this fact, and thus he established the theorem: If the two sets of generators of a hyperboloid be connected by articulated joints wherever they meet, then the system remains movable, the hyperboloid changing its shape. It was also soon found that each point moves during this deformation along the normal to the momentary position of the surface, and that therefore the different positions of the surface constitute a system of confocal hyperboloids. He then made a model such that the generators represented by sticks meet at points which lie on lines of curvature of the hyperboloids. These describe, therefore, confocal ellipsoids and hyperboloids of two sheets. In January 1874, Prof. Henrici exhibited this model at a meeting of the Society. Shortly afterwards a student made two copies of this model, and these were fastened together in such a manner that both could move together, remaining always confocal. It was this last model that was now shown. The properties of the movable hyperboloid became more widely known through a question which Prof. Greenhill set in 1878 at the Mathematical Tripos Examination, and this led Prof. Cayley to give a solution of it in the *Messenger of Mathematics*. Since that time several French mathematicians have made further investigation of the property in question. MM. Darboux and Mannheim, in particular, have made beautiful application of the deformable hyperboloid to the motion of a gyrating rigid body.—The following further communications were made:—The second discriminant of the ternary quantic, $x'u + y'v + z'w$, by Mr. J. E. Campbell. If the ordinary discriminant of this quantic in x, y, z, be formed, the result will be a quantic in x', y', z'. The discriminant of this latter the writer believes vanishes identically with certain exceptions. Prof. Henrici referred the author to a paper by himself in vol. ii. of the Society's Proceedings.—On the reflection and refraction of light from a magnetized transparent medium, by A. B. Basset, F.R.S. The object of this paper is to apply the theory of gyrostatically loaded media, to investigate the reflection and refraction of light at the surface of a magnetized transparent medium. This subject has been partially discussed by Mr. Larmor in a paper communicated to the Society last December, in which he has obtained the equations of motion of the medium; but the paper in question contains (Mr. Basset thinks) a certain amount of vague and obscure argument, founded upon general reasoning, which is calculated to envelop the subject in a cloud of mystery, rather than to enlighten the understanding. He, therefore, finds it necessary to write out the theory *de novo*, and to enter into a careful discussion respecting the boundary conditions. The principal results are as follows: When the magnetic force is parallel to the reflector, and also to the plane of incidence, the expressions for the amplitudes of the reflected light are the same as those which he obtained by means of an extension of the electromagnetic theory (see *Phil. Trans.*, 1891, p. 371); but when the magnetic force is perpendicular to the reflector, the above-mentioned expressions are of the same form as those furnished by the electromagnetic theory, with the exception that the signs of the magnetic terms are reversed. An experimental test of the relative merits of the two theories might probably be obtained by means of certain experiments performed by Prof. Kundt (*Berlin. Sitzungsberichte*, July 10, 1884; translated *Phil. Mag.*, October 1884), but the mathematical work, although presenting no difficulty, would be somewhat laborious. Having worked out these results, he endeavours to obtain a theoretical explanation of Kerr's experiments, on reflection from a magnet, by combining the theory of gyrostatically loaded media with the theory of metallic reflection, explained in his book on "Physical Optics," chapter xviii. sections 386-87; but the results are not entirely satisfactory. This, however, is not surprising, inasmuch as the theory of gyrostatically loaded media takes no account of the statical effects of magnetization.—Note on approximate evolution, by Prof. Lloyd Tanner. This note supplies a deficiency in a paper (Math. Soc. Proc., vol. xviii.) in which Prof. Hill pointed out the incorrectness of the rule for contracting the processes of finding the square and cube roots of a number—namely, it gives a practical test for determining the cases when the rule can, and when it cannot, be safely applied.—A proof of the exactness of Cayley's number of seminvariants of a given type, by Mr. E. B. Elliott, F.R.S.—Further note on automorphic functions, by Prof. W. Burnside.

Royal Meteorological Society, June 15.—Dr. C. Theodore Williams, President, in the chair.—The following papers were read:—English climatology, 1881-1890, by Mr. F. C. Bayard. This is a discussion of the results of the climatological observations made at the Society's stations, and printed in the *Meteorological Record* for the ten years 1881-1890. The instruments at these stations have all been verified, and are exposed under similar conditions, the thermometers being mounted in a Stevenson screen, with their bulbs 4 feet above the ground. The stations are regularly inspected, and the instruments tested by the Assistant Secretary. The stations now number about eighty, but there were only fifty-two which had complete results for the ten years in question. The author has discussed the results from these stations, and given the monthly and yearly means of temperature, humidity, cloud, and rainfall. His general conclusions are:—(1) With respect to mean temperature, the sea coast stations are warm in winter and cool in summer, whilst the inland stations are cold in winter and hot in summer. (2) At all stations the maximum temperature occurs in July or August, and the minimum in December or January. (3) Relative humidity is lowest at the sea coast stations, and highest at the inland ones. (4) The south-western district seems the most cloudy in winter, spring, and autumn, and the southern district the least cloudy in the summer months, and the sea coast stations are, as a rule, less cloudy than the inland ones. (5) Rainfall is smallest in April, and, as a rule, greatest in November, and it increases from east to west.—The mean temperature of the air on each day of the year at the Royal Observatory, Greenwich, on the average of the fifty years 1841 to 1890, by Mr. W. Ellis. The values given in this paper are derived from eye observations from 1841 to 1848, and from the photographic records from 1849 to 1890. The mean annual temperature is 49°·5. The lowest winter temperature, 37°·2, occurs on January 12, and the highest summer temperature, 63°·8, on July 15. The average temperature of the year is reached in spring, on May 2, and in autumn on October 18. The interval during which the temperature is above the average is 169 days, the interval during which it is below the average being 196 days.

SYDNEY.

Royal Society of New South Wales, May 4.—Annual Meeting.—H. C. Russell, F.R.S., President, in the chair.—The report stated that 61 new members had been elected during the year, and the total number on the roll on April 30 was 478. During the year the Society held eight meetings, at which the following papers were read:—Presidential address, by Dr. A. Leibius.—Notes on the large death-rate among Australian sheep in country infected with Cumberland disease or splenic fever, and Notes on a spontaneous disease among Australian rabbits, by Adrien Loir.—Compressed-air flying machines, Nos. 13 and 14, and on a wave-propelled vessel, by L. Hargrave.—A cyclonic storm or tornado in the Gwydir district; Preparations now being made in Sydney Observatory for the photographic chart of the heavens; Notes on some celestial photographs recently taken at Sydney Observatory; and Notes on the rate of growth of some Australian trees, by H. C. Russell, F.R.S.—Some folk-songs and myths from Samoa, translated by the Rev. G. Pratt, with introductions and notes, by Dr. John Fraser.—Notes on the use, construction, and cost of service reservoirs, by C. W. Darley.—On the constitution of the sugar series, by W. M. Hamlet.—On kaolinite from the Hawkesbury Sandstone, by H. G. Smith.—A contribution to the microscopic structure of some Australian rocks, by the Rev. J. Milne Curran.—On some New South Wales and other minerals (note No. 6), by Prof. Liversidge, F.R.S.—Artesian water in New South Wales (preliminary notes), by Prof. T. W. E. David.——The Medical Section held four meetings. The following papers were read :—A brief account of the histology and development of tubercle, by Prof. Anderson Stuart.—Remarks upon the nature and treatment of diphtheria, by Dr. W. Camac Wilkinson.—Glimpses of the past : a series of sketches with pen and pencil of the medical history of Sydney, by Dr. Honison.——The Microscopical Section held five meetings. The following paper was read :—Notes on slicing rocks for microscopical study, by the Rev. J. Milne Curran.——The Civil and Mechanical Engineering Section held eight meetings. The following papers were read :—Recent researches on the strength, elasticity, and endurance of materials of construction with especial reference to iron and steel, by Prof. Warren.—The bridge over Lane Cove River at the head of navigation, by H. H. Dare.—On the calculation of stresses by means of graphic analysis, by J. I. Haycroft.—On the tacheometer and its application to engineering surveys, by W. Poole, Jun.—On the sewerage of country towns : the separate system, by Dr. Ashburton Thompson.——The Clarke Medal for 1892 had been awarded to Prof. W. T. Thiselton Dyer, F.R.S. The Council had issued the following list of subjects with the offer of the Society's bronze medal, and a prize of £25 for each of the best researches if of sufficient merit :—(To be sent in not later than May 1, 1893) Upon the weapons, utensils, and manufactures of the aborigines of Australia and Tasmania ; on the effect of the Australian climate upon the physical development of the Australian-born population ; on the injuries occasioned by insect pests upon introduced trees. (To be sent in not later than May 1, 1894) On the timbers of New South Wales, with special reference to their fitness for use in construction, manufactures, and other similar purposes ; on the raised sea-beaches and kitchen middens on the coast of New South Wales ; on the aboriginal rock-carvings and paintings in New South Wales.—The Chairman read the Presidential address, and the Officers and Council were elected for the ensuing year, Prof. Warren being President.

Paris.

Academy of Sciences, June 13.—M. d'Abbadie in the chair.—A new contribution to the history of the truffle, *Tirmania Cambonii*, "Terfâs" of Southern Algeria, by M. A. Chatin.—On subcutaneous or intra-venous injections of liquid extracts from several organs as a therapeutic method, by MM. Brown-Séquard and d'Arsonval.—In the place of the late Dom Pedro d'Alcantara, M. von Helmholtz was elected Foreign Associate.—Researches on the solar atmosphere, by Mr. George E. Hale, of the Kenwood Astrophysical Observatory, Chicago. A photograph of a metallic protuberance, obtained with an aperture of 12 inches and a large grating spectroscope, shows all the lines previously announced in the ultra-violet, and the following additional ones: 3961·7 (manganese?), 3900·7 (calcium), 3886·4 (hydrogen), and 3860·4 (iron?). The writer has succeeded in photographing faculæ in the centre of the disk.—On the general problem of the deformation of surfaces, by M. L. Raffy.—On the theory of the fuchsian functions, by M. Ludwig Schlesinger.—On transformations in mechanics, by M. P. Painlevé.—On considerations of homogeneity in physics, by M. A. Vaschy.—On the non-realization of the spheroidal state in steam boilers : reclamation of priority, by M. de Swarte.—On the co-existence of dielectric power and electrolytic conductivity, by M. E. Bouty. A rigid condenser is formed of iron disks separated by small wedges of mica, and joined by iron screws isolated by mica and placed opposite the wedges. This condenser is plunged into a fused mixture of equal parts of the nitrates of sodium and potassium. Air bubbles are carefully removed with plates of mica, and the condenser is withdrawn at the moment when the salt commences to solidify. The liquid, retained by capillarity, forms between the disks an adherent regular solid layer. The apparatus while yet hot is plunged into melted paraffin, which surrounds it with an isolating layer devoid of hygroscopic power. The experiments give a value for k approaching 4, and nearly constant within the limits of temperature in which the specific resistance in ohms may vary from $3·6 \times 10^{11}$ to $2·6 \times 10^{9}$, *i.e.* in the ratio of about 138 to 1. Here the conductivity and the dielectric capacity belong to molecules of the same kind. It is probable that, if the experiments could be extended to ordinary electrolytes, they would give results of the same kind—that is, finite values of the dielectric constant k. The distinction between dielectrics and electrolytes would thus solely reside in the amount of their conductivity. Dielectric polarization, established in a very short time in comparison with the ten-thousandth of a second, would correspond, in Grotthuss's scheme, to the initial orientation of the compound molecules, their conductivity to their progressive rupture.—On the retardation in the perception of the different rays of the spectrum, by M. Aug. Charpentier. On suddenly illuminating the slit of a spectroscope by white light, the red portion of the spectrum is seen first, and the light seems to shoot across from the red to the violet. This was confirmed by rotating an inverted sector of a circle, 1 cm. broad at the base, and 8 to 10 cm. long once in two or three seconds. The extreme point seemed drawn out into a kind of spectrum extending from the red to the green. The maximum duration of excitation compatible with the isolation of the colours does not exceed about four or five thousandths of a second.—On the anhydrous crystallized fluorides of nickel and cobalt, by M. C. Poulenc.—Action of nitric oxide upon the metals, and upon the metallic oxides, by MM. Paul Sabatier and J. B. Senderens.—Thermochemical study of guanidine, of its salts and of nitroguanidine, by M. C. Matignon.—Researches on the disodic derivatives of the three isomeric diphenols, by M. de Forcrand.—On normal pyrotartaric or glutaric acid, by M. G. Massol.—Study of the decomposition of the diazo compounds, by MM. J. Hausser and P. Th. Muller.—The folds in the Secondary formations in the neighbourhood of Poitiers, by M. Jules Welsch.—On the genesis of the ophiolitic rocks, by M. L. Mazzuoli.—Three cases of increase in the velocity of transmission of sense-impressions, under the influence of injections of the testicular liquid, by M. Grigorescu.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Country Thoughts for Town Readers: K. B. B. de la Bere (Simpkin).—The Etiology and Pathology of Grouse Disease : Dr. E. Klein (Macmillan).—Marine Shells of South Africa : G. B. Sowerby (Sowerby).—Atlas of Clinical Medicine. vol i. : Dr. B. Bramwell (Edinburgh, Constable).—The Standard Course of Elementary Chemistry, Parts 1–5: E. J. Cox (Arnold).—English Botany, Supplement to the Third Edition, Part 2 : N. E. Brown (Bell).—Volcanoes, Past and Present : Dr. E. Hull (Scott).—Den Norske Nordhaus-Expedition, 1876–78, xxi. Zoologi, Crinoida : D. C. Danielssen (Christiania, Grondahl).—Coal Gas as a Fuel, fourth edition : T. Fletcher (Liverpool, Tinling).

Pamphlets.—Twenty-second Annual Report of the Wellington College Natural Science Society, 1891 (Wellington College).—Johns Hopkins University of Baltimore Register for 1891–92 (Baltimore).—British Universities (Manchester, Cornish).

Serials.—Astronomy and Astro-Physics, June (Northfield, Minnesota).—L'Anthropologie, tome iii. No. 2 (Paris, Masson).—Journal of the Royal Microscopical Society, June (Williams and Norgate).—Contributions from the U.S. National Herbarium, vol. ii., No. 2 (Washington).—Bulletin of the New York Mathematical Society, vol. i. No. 9 (New York).

THURSDAY, JUNE 30, 1892.

THE LONDON UNIVERSITY OF THE FUTURE.

AMONG the many points discussed in relation to the schemes for providing London with a University which have been under consideration during the last few years, scarcely any reference has been made to the higher teaching which ought to be at the disposal of the citizens of the most important and largest city in the world. Attention has been almost exclusively directed to the class teaching necessary to pass certain examinations which open the door to professional employment.

It is not necessary to enlarge upon this remarkable omission, although the reason for it is not far to seek, but we think it may be desirable, in order to show that such teaching is not Utopian, and that other nations freely provide what is so conspicuous by its absence in London, to give an indication of the quantity and quality of the teaching in the metropolis nearest our own.

The indications, to be exhaustive, would occupy several pages of NATURE, we must perforce content ourselves by giving the courses open to the citizens of Paris at the Sorbonne and the Collège de France.

The question does not concern science alone. We have not, therefore, limited ourselves to the scientific subjects; and it will be understood that, besides the undergraduate and graduate courses, there are special courses connected with the many other institutions in Paris allied either with the various professions directly, or with the national culture generally.

Among the former we may content ourselves at present with referring to the École Normal and the École Polytechnique; among the latter are the Museums of Natural History, of Physical Science, of Antiquities, Art and Archæology, each of these with lectures on the subjects which are illustrated by their contents.

We shall, if possible, take a subsequent opportunity of giving lists of these special courses, but the lectures at the University and College alone exhaust our space for this week. Comment on the breadth of the teaching and of the men to whom it is confided in Paris, and on the absence of anything approaching it here, is needless.

SORBONNE: FACULTY OF SCIENCES.

1892—*Second Scholastic Term.*

Day	Hour	Subject	Professor
MONDAYS.	8.30	Differential and Integral Calculus: Ordinary Differential Equations and Equations with Derived Partials	Picard.
	8.45	Lectures on Geology: General ...	Vélain.
	9	Lectures on Chemistry: Manipulations for the Licentiate ...	Riban.
	10	Lectures in Natural Science ...	Chatin.
	10.30	Calculus of Probabilities: Mathematical Theory of Hydrodynamic Vortices and Application to Electrodynamics	Poincaré.
	11	Lectures on Chemistry: Theoretical and Practical Qualitative Analysis	Riban.
	1.30	Lectures on Physical Sciences: Thermodynamics	Pellat.
	2.45	Mineralogy and Crystallography: Principal Mineral Species ...	Hautefeuille.
	3	Lectures on Mathematical Sciences	Puiseux.
	5	Lectures on Chemistry	Joly.
TUESDAYS.	8.30	Astronomy: Programme for the Licentiate's Degree	Wolf.
	8.30	Lectures on Natural Sciences: Botany	Vesque.
	8.30	Lectures on Mineralogy	Jannettaz.
	9	Lectures on Natural Sciences: Identification of Rocks, &c. ...	Vélain.
	10	Mechanics and Experimental Physics: Properties of Elastic Solids, &c.	Boussinesq.
	10	Histology: General Character of Elementary Anatomy; Nervous and Muscular Tissue from an Histological Point of View: Zoology	Chatin.
	10.30	Lectures on Chemistry	Joly.
	2	Physics: Electricity	Lippmann.
	2	Lectures on Mathematical Sciences: Differential and Integral Calculus	Kaffy.
	3	Do. do. do. do.	Kaffy.
	3.30	Zoology, Anatomy, Physiology: Zoophites, &c.	Delage.
	3.30	Course on Spectroscopy and Photographic Chemistry	Salet.
WEDNESDAYS.	8.30	Mechanics. Dynamics of Systems	Appell.
	8.45	Lectures on General Geology ...	Velain.
	9	Lectures on Chemistry: Manipulations for the Licentiate ...	Riban.
	10.15	Higher Algebra: Theory of Euler's Integrals and Functions of a Variable	Hermite.
	1.30	Organic Chemistry: Compounds of the Aromatic Series	Friedel.
	2	Lectures on Mathematical Sciences	Blutel.
	3	Geology: Principal Characters of Geological Periods; Geological Formations	Munier-Chalma
	3	Lectures on Mechanics and Astronomy	Puiseux.
	3.45	Analytical Chemistry: Determination and Separation of Metals...	Riban.
	4	Lectures on Physical Sciences: Questions on the Subjects of Prof. Lippmann's Cours ...	Foussereau.
THURSDAYS.	8.30	Lectures on Physical Sciences. Thermodynamics	Pellat.
	8.30	Differential and Integral Calculus, &c.	Picard.
	9	Lectures on Natural Science: Identification of Rocks and the Principal Characteristic Fossils	Velain.
	9	Lectures on Chemistry: Manipulations for the Licentiate ...	Riban.
	10	Lectures on Natural Science ...	Chatin.
	10.30	Calculus of Probabilities and Mathematical Physics: Theory of Vortices. Hydrodynamics: Application to Electrodynamics	Poincaré.
	1	Chemistry Lectures and Manipulations for Professors of Colleges	Riban.
	1.30	Lectures on Physical Sciences: Reflection and Refraction of Light	Foussereau.
	1.30	Lectures on Mathematical Sciences as a Whole	Kœnigs.
	2.30	Do. do. do. do.	Kœnigs.
	2.45	Mineralogy and Crystallography, &c.	Hautefeuille.
	4	Lectures on Physical Sciences ...	Pellat.
	5	Lectures on Chemical Sciences ...	Joly.

Day	Hour	Subject	Professor
FRIDAYS.	8.30	Lectures on Physics	Pellat.
	8.30	Mechanics: Dynamics of Systems	Appell.
	8.30	Lectures on Botany	Vesque.
	9	Lectures on Chemistry and Manipulations for the Licentiate	Riban.
	9	Lectures on Geology: Identification of Rocks and the Principal Characteristic Fossils	Velain.
	10	Mechanical and Experimental Physics, &c.	Boussinesq.
	10.30	Organic Chemistry: Compounds of the Aromatic Series	Friedel.

	10.15	Higher Algebra: Euler's Integrals, &c.	Hermite.
	10.30	Lectures on Chemistry	Joly.
	2	Physics: Electricity	Lippmann.
	3	Lectures on Mathematical Sciences: Mechanics and Astronomy	Puiseux.
	3.30	Zoology, Anatomy, Comparative Physiology	Delage.
	3.30	Lectures on Organic Chemistry	Salet.

FACULTY OF LETTERS. 1892—*Second Term.*

Day	Hour	Subject	Professor
MONDAYS.	9.30	Lectures on French Literature	Gazier.
	11	Complementary Course in English Language and Literature	Beljame.
	1.15	Pedagogy Lectures (Historical Sciences), General Contemporaneous History	Seignobos.
	1.30	History of Ancient Philosophy: Moral and Political Doctrines of Aristotle	Waddington.
	1.30	Lectures on French Literature	Gazier.
	1.30	Lectures on German Language and Literature: History of the German Language	Lange.
	1.30	Lectures on Latin Language and Literature	Lafaye.
	2	History Lectures: General History of the Seventeenth and Eighteenth Centuries	Zeller.
	2.30	French Literature of the Middle Ages: History of the French Language: History of Literature in France in the Fourteenth Century. Froissart	Julleville.
	3	Latin Language and Literature	Lafaye.
	3	Greek Eloquence: Greek Moralist Writers	Croiset.
	3	Foreign Literature: Æsthetic and Moral Literature of Goethe; General Character of Faust	Lichtenberger.
	3	Modern History: History of Legislation from the Sixteenth to the Eighteenth Centuries	Lemonnier.
	3.30	Literature of Southern Europe: Cervantes's Works	Gebhart.
	4	History of Philosophy: Modern Texts	Boutroux.
	4	Modern History: Practical Exercises	Lemonnier.
	4.15	Modern and Contemporaneous History: History of Russia in the Sixteenth Century	Rambaud.
	5	History of Modern Philosophy: Texts	Boutroux.

Day	Hour	Subject	Professor
TUESDAYS.	9	French Literature: Practical Exercises	Larroumet.
	8.45	Ancient History: Commentary on a Text	Bouché Leclercq.
	9	Sanskrit, and Comparative Grammar of the Indo-European Languages, &c.	Henry.
	9.45	Ancient History; Greek and Roman Institutions	Bouché Leclercq.
	10	History of Ancient Philosophy	Waddington.
	10-11	Latin Poetry: Practical Exercises	Cartault.
	10.15	French Poetry; Explanation of one of the Authors from the Licentiate and Fellowship Programme	Lenient.
	10.30	History: Practical Exercises	Zeller.
	1.30	Discourses on Contemporaneous Philosophy	Janet.
	1.45	Ancient History: History of the Roman Empire from the Time of Nero	Guiraud.
	2	Letters of Southern Europe: Dante	Gebhart.
	2	Greek Language and Literature	Hauvette.
	3	Geography: History of the Exploration of America since Columbus, &c.	Himly.
	3	French Literature: Practical Excises	Larroumet.
	3.15	Latin Language and Literature: History of Latin Literature	Lafaye.
	4.15	Greek Language and Literature	Hauvette.
	4.45	History of Philosophy: Systems of Spinoza and Malebranche	Brochard.
WEDNESDAYS.	9	French Eloquence	Crouslé.
	9.15	Pedagogy (Historical Sciences)	Seignobos.
	9.30	Sanskrit: Relations of India with the West	Levi.
	10	Archæology: History of Vase-painting in Greece	Collignon.
	10.30	Philosophy	Janet.
	11	Archæology: Practical Exercises in Archæology	Collignon.
	1	Latin Eloquence: on Roman Eloquence under the Republic	Martha.
	1.30	Ancient History	Guiraud.
	1.30	French Literature: French Literature in the Seventeenth Century	Gazier.
	1.30	Mental Philosophy	Seailles.
	2.15	History of French Colonization and Beginning of the French Restoration	Pigeonneau.
	2.30	Ancient History: Practical Exercises	Guiraud.
	2.30	Philosophy	Seailles.
	2.45	Philology and Metre: Written and Oral Exercises on Metre	Havet.
	3.30	History of the French Revolution: History of the National Constitution	Aulard.
	3.30	Sanskrit, and Comparative Grammar of the Indo-European Languages	Henry.
	4	History: Practical Exercises	Pigeonneau
	4	Greek Poetry: Lyric Element of Greek Tragedy	Decharme
	4.45	History of Modern Philosophy: Idea of Natural Law, &c.	Boutroux.
	5	Sanskrit, and Comparative Grammar of the Indo-European Languages	Henry.
	5	English Language and Literature	Baret.

Day	Hour	Subject	Professor
Thursdays.	8.30	History of the French Revolution: Exercises	Aulard.
	9	Greek Literature and Institutions: Correction of Greek Themes, &c.	Girard.
	9.30	History of the French Revolution: Explanation of Titles	Aulard.
	9.30	Lectures on the History of Philosophy: Practical Exercises	Brochard.
	10	Latin Poetry: Passages from Lucretius	Cartault.
	10	Lectures on English Language and Literature: Practical Exercises	Baret.
	10.15	Lectures on Greek Literature and History: Explanation of the Authors in the Programme	Girard.
	10.30	Lectures on the History of Philosophy	Brochard.
	10.45	History Lectures: Bassoinpierre's Memoirs	Zeller.
	1	English Language and Literature: Shakespeare—French Literature	Beljame.
	1.30	Lectures on German Language and Literature: Correction of Themes and Dissertations	Lange.
	2	French Poetry: Patriotic Poetry in France since the 16th Century	Lenient.
	2	English Language and Literature: Othello	Beljame.
	2	Roman Philology: First Chapters of Dante's Inferno	Thomas.
	3	Foreign Literature: Preparation for the Examination in German	Lichtenberger.
	3	Modern History: Relation of French Art to Institutions, &c.	Lemonnier.
	3.30	French Literature of the Middle Ages	Julleville.
	4	Foreign Literature: Preparation for the Examination in German	Lichtenberger.
	4.15	Geography: History of the Exploration of America since Columbus	Himly.
Fridays.	9	Course of Roman Philology: Explanation of Texts with French, &c.	Thomas.
	9	Complementary Course: Auxiliary Sciences—on the History of Latin Literature	Langlois.
	9.15	Latin Eloquence: Explanation of Latin Authors	Martha.
	9.30	Complementary Course in Sanskrit: Explanation of Elementary Texts	S. Levi.
	10	Complementary Course in Philology and Metre: on Metre	Havet.
	10	Complementary Course of Roman Philology: History of the Literature	Thomas.
	10.15	Lectures on Pedagogy: Theory of History Teaching	Seignobos.
	1	Lectures on Greek Language and Literature: History of Greek Literature	Hauvette.
	2.30	Greek Poetry: Explanation of Texts, and Practical Exercises	Decharme.
	2.30	History of the Middle Ages: on French Ecclesiastical Institutions	Luchaire.
	3.30	Practical Exercises in History	Luchaire.
	3 30	Ancient History: History of Rome from Scylla to Cæsar	BouchéLeclercq
	3.30	Greek Poetry: Explanation of Texts, and Practical Exercises	Decharme.
	4	Modern and Contemporaneous History: History of the Hindus under Queen Victoria	Rambaud.
	4.15	French Literature (Complementary Course): History of French Literature in the 18th Century	Larroumet.
	4.45	Lectures on Geography: Text of the Programme	Dubois.
Saturdays.	9	Greek Eloquence: Explanation of Greek Texts and Letters, &c.	Croiset.
	9	Complementary Course: Auxiliary Sciences—on the History of Palæography	Langlois.
	10	Complementary Course in Literature: on the Archæology of the Middle Ages	Langlois.
	10.15	French Eloquence: French Writers of Prose in the Nineteenth Century	Croiset.
	10.15	Lectures on Greek Literature and History: History of Greek Poetry since the Fifth Century	Girard.
	1.30	Greek Eloquence: Practical Exercises	Crouslé.
	1.30	Lectures on German Language and Literature	Lange.
	1.30	Lectures on Philosophy	Seailles.
	2	Lectures on Geography: Various Questions in General Geography	Dubois.
	3	Latin Poetry: Lucretius and Latin Poetry during the Ciceronian Epoch	Cartault.
	3	Archæology: Sculpture in Greece to the Fifth Century	Collignon.
	3	Lectures on Geography: Practical Exercises	Dubois.
	4	History: History of the Doctrine of Economics during the first part of the Nineteenth Century	Pigeonneau.

Collège de France.

1892—*Second Term.*

Day	Hour	Subject	Professor
Mondays.	9	Modern Philosophy: concerning the Soul	Nourrisson.
	9	Natural History of Inorganic Bodies	Fouqué.
	10	Language and Literature of the Arabs: Moallakat and Divans of Six Poets	B. de Meynard.
	10.15	Æsthetics and History of Art: History of Italian Art under Pius II.	Lafenestre.
	10.15	Celtic Languages and Literature: Ancient and Middle Irish Texts	H. d'Arbois de Jubainville.
	10.30	Organic Chemistry: on Organic Synthesis and Hydrocarbons	Berthelot.
	11.15	Comparative Grammar: Theory of the Verb in Indo-European Languages	Bréal.
	12.30	Egyptian Philology and Archæology: Pyramid Texts	Maspero.
	1.30	History of Latin Literature: History of the Latin Theatre	Boissier.
	2.30	Greek Epigraphy and Antiquities: Athenian Constitution of Aristotle	Foucart.
	3	History of Religion: History of Judaism during the last Four Centuries of the Christian Era	Réville.
	3.15	Experimental and Comparative Psychology: Will, Heredity, Perception	Ribot.
	3.30	Semitic Epigraphy and Antiquities, with Epigraphic Texts	Clermont-Ganneau.
	4.45	Latin Philology: on the Prosody of Vowels in the Latin Language	Havet.

Day	Hour	Subject	Professor
Tuesdays.	9	History of Latin Literature	Boissier.

ENGLISH BOTANY.

English Botany. Supplement to the Third Edition. Part I. (Orders I.–XXII.). Compiled and Illustrated by N. E. Brown, of the Royal Herbarium, Kew. Pp. 56, viii., 6 Plates. (London: Bell and Sons, 1891 [1892].)

THE third edition of "English Botany" was begun just thirty years since by Dr. Boswell (then Syme), and continued at somewhat uncertain intervals, the flowering plants being completed in 1872. The ferns followed at a later period, and the volume containing them was completed by Mr. N. E. Brown, owing to the failure of Dr. Boswell's health.

Although styled a third edition, Dr. Boswell's work was, as everyone knows, a thoroughly new book. It was the production of one who knew plants in the field as well as in the herbarium, and who had a firm hold of his subject. Mr. J. G. Baker, who speaks with authority in matters of this kind, says:—

> "It is not alone the fulness and accuracy of the descriptions that make the book so valuable, but the power he shows in grasping the relationship of the types, and the acute sense of proportion shown in their arrangement. . . . I never cease, when I use the book, to admire the skill which is shown in dividing out the types into species, sub-species, and varieties—a task that was done so thoroughly well that when Sir J. D. Hooker, with all his wide experience, went over the same ground shortly after, in his 'Student's Flora,' he found extremely little to change."[1]

The book, indeed, had defects, among which may be mentioned the "popular portion" and the bad colouring of the plates, but for these Dr. Boswell was not responsible: and although the history of our British flora may seem to some to have received less attention than it merited, the author's work well deserves the high praise which Mr. Baker bestowed upon it.

The first part of the "Supplement," now before us, is the work of Mr. N. E. Brown. Mr. Brown has long been recognized as an authority upon certain difficult groups of plants. He has probably a greater knowledge of the *Stapelieæ*, for instance, than any man living; he has done much good work among the *Aroideæ;* and his many years' employment in the Kew Herbarium has been productive of other valuable contributions to systematic botany. He is careful and painstaking, and a fair draughtsman. Yet with all these qualifications he is not the man to whom the "Supplement to English Botany" should have been entrusted. Such a task could only be carried out satisfactorily by one whose knowledge of British plants was based upon an acquaintance with them in the field as well as in the herbarium, and Mr. Brown's name does not occur to us in this connection.

There was, as it seems to us, one way, and only one, in which a "Supplement to English Botany" could have been done satisfactorily. During the last thirty years our flora has received many additions of *bonâ fide* types; these should, of course, have been figured and described. Having regard to the execution of the third edition, the novelties in certain critical genera—such as *Rubus* and *Hieracium*—might have found a place; although the correlation of English with continental forms which is still proceeding in the former genus, and the (too slow) publication of Mr. F. J. Hanbury's monograph in the latter, would have justified their partial if not entire exclusion. But the attempt to put into the old bottles the new wine of recent research could only result, as it has resulted, in failure. The Batrachian Ranunculi, for instance, may not have been treated satisfactorily by Dr. Boswell; and Mr. Brown perhaps does well to reproduce a subsequent note by that author modifying his views. But the treatment as it stood was a consistent piece of work—the expression of the opinion of one man. Mr. Brown endeavours to fit Mr. Hiern's well-known paper on these plants into Dr. Boswell's original descriptions—a Procrustean undertaking, and one which, in our judgment, is entirely valueless, representing as it does neither Dr. Boswell's, Mr. Hiern's, nor any other consistent view about these troublesome plants. Mr. Brown's style is so terribly involved that it is often very difficult to ascertain what he means; and he would have been far wiser had he left the Batrachian buttercups alone.

For his rearrangement of *Thalictrum* he made "a careful examination of all the material at [his] disposal." It will hardly be believed that neither in this nor in any other instance has he taken the trouble to consult Dr. Boswell's own herbarium, although this, as Mr. Brown must know, is readily accessible to all London botanists. The craze—we can use no milder term—for burdening our lists with varietal names on the most trivial pretexts receives Mr. Brown's support: he resuscitates Pritzel's names for the bluish and reddish-flowered forms of *Anemone nemorosa* (identifying the former with the *A. Robinsoniana* of gardens), although he adds that they are "mere colour forms," with "numerous intermediate shades." Mr. Melvill's name is attached to a "var. *rosea*" of *Silene gallica*, although he did not rank it as such, but referred to it as a "form merging by every gradation into" *quinquevulnera;* and Mr. Brown enriches our nomenclature with a new name—"*Silene anglica* var. *maculata*, N.E. Br."

Speaking of Mr. Pryor's var. *oleracea* of *Silene Cucubalus*, Mr. Brown says:—

> "If the plant intended is the same as *S. inflata* var. *oleracea*, Ficinus, 'Flora der Gegend um Dresden,' ed. 2, vol. i. p. 313 (1821), which is figured in Reichenbach, Icones Fl. Germ. et Helvet., vol. vi. pl. 300, f. 5120 γ, it is," &c.

Now, Mr. Pryor appends to his varietal name a reference to "Bor. Fl. Centr., ed. iii., ii., 95," and Boreau cites Reichenbach's t. 300 for his plant. How, then, can there be any question as to the plant "intended"? If Mr. Brown means to say that he is doubtful as to the accuracy of Mr. Pryor's identification, that is, of course, another matter.

Prof. L. H. Bailey lately spoke with deserved severity of certain "authors of local floras" as obtaining "a cheap notoriety by making new combinations" in nomenclature; and no one can glance through this "Supplement," or refer to the pages wasted in discussing the nomenclature of *Corydalis* and *Spergularia*, without applying his remarks, to the compiler thereof.

Much space is also taken up, and in our opinion wasted by the relegation of species to other genera than those in which they were placed by Dr. Boswell. The following note on "*Lychnis alba*, Mill.," is an illustration of this, and will serve at the same time as an example of Mr. Brown's style:—

---

[1] *Journal of Botany*, 1888, p. 83.

> "This is the *Silene pratensis* of vol. ii. p. 67, but, together with *S. diurna* of p. 69, should be referred to the genus *Lychnis*, where they properly belong; *S. diurna* being *Lychnis dioica*, Linn.; this name has been objected to on the ground that Linnæus included *L. alba* as a variety of *L. dioica*, which objection is untenable as it appears to me; still, if Linnæus's name is rejected, then *L. diœcia*, Miller ('Gardener's Dictionary,' ed. 8, No. 3, errata, 1768), must take precedence over *L. diurna*, Sibthorp ('Flora Oxoniensis,' p. 145, 1794)."

Here is another example:—

> "*Geranium striatum*, Linn. This plant was first published by Linnæus as *Geranium versicolor* in his 'Centuria I. Plantarum,' p. 21 (1755); but in 1759, when this same Centuria was republished in his 'Amœnitates Academicæ,' vol. iv., he altered the name to *G. striatum*, p. 282, which name was retained by Linnæus in all his later works, so that in all probability Linnæus regarded the name *G. versicolor* as a clerical error, which appears to me a consistent view to take of the case, the more so as it is also probable that the original Centurias were only printed for a restricted, or possibly private, distribution."

It is evident, in spite of all its defects, that Mr. Brown has lavished—we do not like to use a stronger expression—a great deal of time and trouble over this "Supplement." A less careful worker, indeed, might easily have produced a better book; for the trivial corrections and emendations, the questions of synonymy, the minute criticisms, and the unnecessary additions, would not have been put forward by any save the most conscientious of writers. There is an appendix of "additions and corrections," occupying an eighth of the whole, but, at any rate so far as "corrections" are concerned, far from exhaustive. And yet, with all this elaboration, the book is not as complete as it should be. The remarkable *Sagina* described in 1887 by Dr. F. Buchanan White as *S. Boydii* is not figured, and Mr. Brown has not even seen a specimen of the plant. Mr. Boyd has had it in cultivation for several years, and would, we doubt not, have supplied examples; and it is not easy to understand why Mr. Brown omitted to make himself acquainted with this very striking form. The plates are mostly poor: to one there is no reference in the letterpress; another is wrongly numbered.

Since the foregoing was written, the second part of the "Supplement" has appeared. It is mainly occupied with the Rose and Brambles, concerning which Mr. Brown says, "I express no opinion, as I have never made any attempt whatever to study them." This is commendably candid, but adds materially to the difficulty of understanding why Mr. Brown was selected for the work, while it deprives the compilation of value. JAMES BRITTEN.

A BACTERIOLOGICAL HAND-BOOK.

Bacteriologisches Practicum zur Einführung in die practischwichtigen bacteriologischen Untersuchungsmethoden für Aerzte, Apotheker, Studirende. By Dr. W. Migula. (Karlsruhe: Otto Nemnich, 1892.)

ALTHOUGH a knowledge of bacteriological methods is essential not only to those who seriously take up the study of bacteria, but also to many who, like the candidates for the diploma of public health, take but a compulsory glance at bacteriology, yet the supply of manuals describing the details of bacteriological practice is remarkably meagre.

Dr. Migula's little book should, therefore, prove very welcome to the bacteriological student, for it does not aspire to be an exhaustive work on bacteria in general, the list of which is receiving constant additions, but aims at describing simply and carefully in a handy form the principal methods of working with micro-organisms.

A number of varieties are more or less elaborately given, but the main idea has been to seek out characteristic forms which are intended to serve as types to illustrate the various points dealt with in the treatment of bacteria.

All the stages in the laboratory life-history of a micro-organism are elaborately entered into, and special chapters are devoted to the formation and staining of spores, and also to the nature of the flagella and most improved methods of exhibiting them in microscopic preparations. The latter are beautifully displayed in a photograph, showing the numerous flagella attached to the typhoid bacilli. The preparation of the various culture-media is described very minutely, and there are many useful laboratory hints and it is the more surprising, therefore, to find the method of sterilizing milk without altering its chemical composition omitted. This mode of preparing milk is naturally of importance in any inquiry as to the vitality of pathogenic micro-organisms in this medium. Again, the plan of cultivating bacteria on potatoes in tubes is not given, although it presents many decided advantages over the "dish method."

Dr. Migula repeatedly insists upon the necessity of unremitting care in carrying out all bacteriological operations to prevent the access of contamination either from the air or by contact with unsterilized or imperfectly sterilized objects. Such precautions are naturally of the utmost importance, but possibly it is unnecessary to warn students against contaminating their platinum needle through testing its temperature after heating by placing it to their lips. Such a proceeding, if ever attempted, would certainly not be quickly repeated!

But there is one piece of advice upon which the author lays great stress, and which in our opinion is not only unnecessary, but a constant menace to success. On almost every page, in one capacity or another, we find the use of corrosive sublimate most strongly recommended as a means of assisting sterilization and of affording additional protection from external contamination. It cannot be impressed strongly enough upon the student that he must depend for the success of his cultivations, not on the use of *antiseptics*, but by working on strictly *aseptic* principles, through the most conscientious devotion to every detail and precaution with which he is acquainted. The fear of contamination must ever appear to him as threatening as the "sword of Damocles," which will descend with unerring certainty as soon as the least evidence of relaxation is visible. Not only is the use of corrosive sublimate demoralizing, then, but on account of its very germicidal properties, unless handled with the utmost care, will prove a positive danger, destroying where it is least expected or wanted. This opinion is unfortunately the result of experience and not of mere imagination.

The examination of water is given *in extenso*, but there is no mention, when discussing the presence of typhoid bacilli in water, of the latest methods for their detection amongst other micro-organisms contained in natural waters.

The investigation of air for micro-organisms is entirely left out, an omission which renders the book less complete than it would otherwise appear to be.

But there is a great deal of instruction, together with many valuable hints, contained in the comparatively short space of 200 pages; and whilst, interspersed in the text, wood-cuts serve to supplement some of the descriptions of apparatus, it also boasts some very good photographs from original preparations of the *Staphylococcus pyogenes citreus*, the *Streptococcus erysipelatis*, the *Bacillus anthracis* with spores, the tuberculosis Bacillus, Koch's comma Spirillum, and others.

There is also appended a useful list of all the requisite appliances for bacteriological work.

GRACE C. FRANKLAND.

OUR BOOK SHELF.

Neue Rechnungsmethoden der Höheren Mathematik. Von Dr. Julius Bergbohm. (Stuttgart: Selbstverlag des Verfassers, 1892.)

Neue Integrationsmethoden auf Grund der Potenzial-, Logarithmal-, und Numeralrechnung. (The same.)

THE first of these pamphlets contains an account of what the author calls the *Immensalrechnung*, the *Potenzialrechnung*, the *Radikalrechnung*, the *Logarithmalrechnung*, and the *Numeralrechnung*. In the *Immensalrechnung* an attempt is made to provide a calculus of the infinitely great (*das Immensal*), which shall form a complement to the differential calculus, or calculus of the infinitely small. The *Potenzialrechnung* contains an account of exponential functions in which the base is an infinitely small or an infinitely great quantity, and the exponent is infinitely small; and the *Radikalrechnung* an account of the inverse functions that are obtained from these by changing the exponent into its reciprocal. So, too, in the *Logarithmalrechnung*, logarithmic functions are considered in which the base and the argument are either infinitely small or infinitely great; and in the *Numeralrechnung* the inverse functions (antilogarithms or exponential functions) are discussed. The pamphlet is occupied, for the most part, with an exposition of the author's notation, a discussion of certain indeterminate forms, and a calculation of some algebraic functions containing an infinitely small argument, to a first, second, or third approximation. It is hardly possible to compliment the author on his accuracy, seeing that the statement occurs that Lt. log x is finite when x is zero or infinity, the reason given being that Lt. ($x \log x$) and Lt. ($\log x/x$) are zero, for these values of x.

The second pamphlet begins with a *résumé* of some of the results of the first one; and then proceeds to discuss the application of these results to the evaluation of certain elementary integrals. The author's avowed object is to provide a method for the direct calculation of integrals, comparable with that now employed in differentiation, so that it may no longer be necessary to resort to the indirect methods of integration at present employed. It is impossible to deny that the object is a laudable one; but, to judge from the examples given in this pamphlet, it does not seem likely that the method will be of much use in the case of integrals of any degree of complexity. Dr. Bergbohm promises to supply us in the future with further examples of the application of his methods; but, until these have appeared, it is hardly possible to say that students of mathematics will find these pamphlets repay them for the trouble of reading them and of mastering the author's notation.

R. E. A.

An Elementary Course in Theory of Equations. By C. H. Chapman, Ph.D. (New York: John Wiley and Sons, 1892.)

THIS is really an excellent little book, but is rather misnamed in being called an elementary treatise. The study of the theory of equations, although generally expanded far too considerably, is here dealt with in rather the reverse way, the treatment being somewhat too curt. For anyone beginning this subject the book would be found slightly difficult, but for a student who has already had a little experience in this direction, it should prove a very useful *vade mecum*, for the author has brought together in a few pages just those portions of the subject that are required in actual practice. The three sections treat respectively of determinants, algebraical equations, and the methods by which the real roots of numerical equations are computed, and they are each accompanied by numerous examples.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"The Grammar of Science."

IT is very idle as a rule to criticize a critic, especially when he happens, like C. G. K., to be the disciple of a school which the author of the criticized work is gently laughing at throughout his pages. But some of C. G. K.'s remarks might lead your readers to believe that the "Grammar of Science" is nonsense, even when looked at without the spectacles of the Edinburgh physical school, and his review may therefore justly call for a few words of reply.

Because C. G. K. found himself entirely unable to follow my argument as to the universality of scientific law, he was hardly justified in putting an antecedent before a consequent, and making nonsense of it. The universality of scientific law depends on the similarity of the perceptions and of the reflective faculties in normal civilized man. Why does this similarity exist? asks C. G. K.; and then turns for an answer to an antecedent in the argument—namely, that a condition of this universality is the similarity in those perceptions and reflective faculties. As a matter of fact in the "Grammar" itself, it is pointed out that a society of beings with different perceptions and reflective faculties could hardly survive in the struggle for existence with societies where there was an approach to similarity; that as soon as the divergence reaches a certain magnitude we lock up the individual as a madman or an idiot, or, in milder cases, bring great social pressure to bear upon him, and mould him to the ordinary standard.

"The laws of Nature are a mental product, yet a certain evolution theory logically based upon them quite eliminates the mental," writes C. G. K. of the "Grammar." Where he found this statement I know not, but what the "Grammar" itself states is: that the laws of evolution are themselves a mental product, a description in shorthand of the sense-impressions and stored sense-impresses of the mind at a given instant. They are a mental mode of briefly classifying sense-impressions, and not inherent in something behind sense-impressions themselves.

C. G. K. then quotes my statements as to Maxwell's descriptions of energy and matter. Now what the "Grammar" says is that Maxwell's statements are "extremely valuable as expressing concisely the nature of certain conceptual processes by aid of which we describe certain phases of our perceptual experience, but as defining matter they carry us no further than the statement that matter is that which moves," or indeed than Prof. Tait's statement that "matter is that which occupies space." The whole object of the investigation is to show that mass, but *not* matter, is capable of definition. As Clerk Maxwell tells us that his statements contain all we *know* of matter and energy, it is clear that these are the only statements by way of *definition* which he conceives it advisable to give of them, and *they are all he does give.* I happened to be one of the unfortunate Cambridge students whose first notions of matter and force were obtained from the "Treatise on the Dynamics of a Particle," and it was therefore a relief to me when I met with Kirchhoff's "Mechanik" in 1876, and found the subjectivity of force clearly insisted on. That view of force was in the air of Berlin when I was a student there in 1879. Kirchhoff's services in this matter are referred to with special emphasis on p. 139 of the "Grammar." A perfectly consistent view of force and matter had been published by Mach in 1883. Why the fact that Prof. Tait put forward the "subjectivity of force" in a work of 1885 makes me therefore "a disciple of Prof. Tait," I fail to understand. This statement is the more astonishing, as Prof. Tait directly postulates the "objectivity of matter," but in the same work tells us that "matter is, as it were, the plaything of force." How subjective force can have an objective plaything, perhaps C. G. K. will inform us; but the statement clearly marks off the standpoint of the "Grammar" from that of Prof. Tait. Mass, according to the "Grammar," can only be defined as the ratio of mutual accelerations, and any attempt to connect it with the "quantity of matter" in a body is asserted to be unphilosophical. C. G. K. asks if a passage he quotes from Tait's "Properties of Matter" is not *essentially* the theory of "ether-squirts"? I reply *No*, the words "*constantly* swallows up an amount proportional to its mass," or "at a rate proportional to its mass," sufficing to exclude the mutually enforced flows of ether on which the "Grammarian" bases his applications of ether-squirts to chemical and cohesive actions (*American Journal of Mathematics*, vol. xiii., pp. 309–62). Had I ever read, or if read, recollected, Sir William Thomson's suggestion, it would have been referred to, and a reference to him will be introduced into later editions of the "Grammar."

C. G. K. very skilfully tries to turn off the "Grammarian's" criticism of the Edinburgh school by representing it as an attack on Newton. The words in the "Grammar" are: "Remembering these points we will now turn *to the version of the Newtonian laws given by Thomson and Tait*" (p. 381). Force, say our writers, is any cause that tends to alter a body's natural state of rest, or of uniform motion in a straight line; but force, says Prof. Tait, is *subjective*, and corresponds to nothing which exists outside ourselves. Surely it is a "veritable metaphysical somersault" to then assert that it can be "applied in a straight line"? I fail completely to see how the view that force is subjective is consonant with the definitions and laws put forward by Thomson and Tait, and asserted by them to be Newtonian. With regard to Newton's own statements, I openly declare that, with all admiration for his genius, I doubt the logical sequence and accuracy of many of his statements with regard to the philosophical basis of dynamics. Those who would bind down all time to his views on matter, force, and motion, are much like the geometricians who think it impious to cast out Euclid from school-teaching. Both Euclid and Newton have handed down to us in their pages discoveries which will always form a portion of man's intellectual heritage, but the method in which those discoveries are presented will vary from age to age with increasing clearness in man's conceptions of mental and physical processes.

Finally, C. G. K. remarks that my conclusions are "materialistic," by which term I suppose he means that he disagrees with them. As one of the chief objects of the "Grammar" is to cast the term *matter* forth from scientific language, it would have been more correct to say that my conclusions are "idealistic." I fear C. G. K. has a more supreme contempt than the majority of the countrymen of Reid and Hume for an accurate use of philosophical language. KARL PEARSON.

Immunity of the African Negro from Yellow Fever.

THIS point, interesting to anthropologists, is raised anew by a writer on the history of epidemics (NATURE, June 16), who asks whether the alleged protection is supported by all recent authorities. Recent authorities are not so well placed for judging of this matter as the earlier; for the reason that immunity is not alleged except for the African negro of pure blood or unchanged racial characters, and that these conditions of the problem have been much less frequently satisfied in the yellow-fever harbours of the western hemisphere since the African slave trade ceased. However, there was a good opportunity in 1866, during the disastrous yellow fever among the French troops of the Mexican expedition when they lay at Vera Cruz. Among them was a regiment of Nubians, who had been enlisted for the expedition by permission of the Khedive: that regiment had not a single case of yellow fever all through the epidemic. The African negro regiment brought over from the French colonies of Martinique and Guadeloupe had two or three cases, with, I think, one death. The rest of the troops, including Frenchmen, Arabs from Algeria, native Mexicans and Creoles, had no immunity whatever, but, on the other hand, a most disastrous fatality. The medical officers of the French service have recorded the facts principally in the *Archives de Médecine Navale*, their conclusion as to racial immunity being the same that has passed current among the earlier authorities as a truth of high general value (admitting, of course, of exceptions in special circumstances), and a truth that has never, so far as I know, been formally controverted by anyone, although other points concerning yellow fever have been the subject of as obstinate controversy as those touching small-pox itself. The experiences of the French at Gorée, a town with ten times as many negroes as whites, exactly confirmed those of Vera Cruz in the same year (*Arch. de Méd. nav.*, ix. 343).

The immunity of the African negro from yellow fever has become a paragraph in some anthropological text-books. ~~It is~~ from the anthropologists, and not from medical authorities, that Darwin cites the fact in his "Descent of Man," adding an original theory of the immunity, which he was unable to establish after much inquiry. His theory, I need hardly say, was not that "negroes in infancy may have passed through some disease too slight to be recognized as yellow fever,"—whatever that may mean—"but which seems to confer immunity." The theory, however, is another story, or "another volume," as the writer just cited is pleased to suggest; and as for the historical fact of immunity, no one denies it, unless it be Dr. Pye Smith in his recent Lumleian lectures (*Lancet*, April 23, 1892, p. 901), who gives no reasons.

It is unfortunate that the anthropologists (Darwin among them) should have introduced one element of dubiety in placing mulattoes on the same footing, in respect of immunity, as negroes of pure descent, and another in mixing up malarial or climatic fevers with yellow fever. C. CREIGHTON.

June 20.

The Line Spectra of the Elements.

I SEE by Prof. Stoney's letter that I have not yet succeeded in making myself understood, as he does not enter on the subject of my objection. A function of the time may well, with any assigned degree of accuracy and for any length of time, be approximately represented by a sum of circular functions, and nevertheless the periods, amplitudes, and phases may not approach definite values when the length of time for which the approximation is to hold good is increased indefinitely. I think this is quite clear from the example I have given in my last letter (p. 100), and it is not necessary to write out other examples. Now, Prof. Stoney shows how one may find by Fourier's theorem the amplitudes, periods, and phases of a sum of circular functions if one only knows the values of the sum. This deduction is not new to me. I worked out the same equations in a slightly different form, when Prof. Stoney's first letter made me further think about the subject. The deduction does also apply to functions that are approximately represented by a sum of circular functions, but *only under the restriction* that the time for which the approximation holds good is long in comparison to the longest period of the circular functions. In chapter iv. of his paper "On the Cause of Double Lines, &c." (Transactions of the Royal Dublin Society, 1891), Prof. Stoney should have added this restriction. Then the question would naturally have arisen how the restriction follows from Prof. Stoney's hypothesis on the origin of the line spectra. I do not venture to say that it does not, but the author would have to prove it.

Technische Hochschule, Hannover.

The Nitric Organisms.

I MUCH regret to learn from your last issue that Mr. Warington considers that I failed to do justice to his work on this subject in my recent lecture at the Royal Institution, and which was reprinted in your columns of the 9th inst. Mr. Warington complains that I have attributed to Winogradsky, and not to himself, the separation of the nitric ferment; I think, however, that Mr. Warington does not correctly understand the sense in which I employ the word "separate," or rather "isolate" (that is the exact word which I did use), for it does not appear to me that Mr. Warington has ever claimed to have *isolated* this ferment; thus, on referring again to his most recent publication on this subject, I read, "An attempt to isolate the nitric organism by the dilution method failed, but apparently only one other organism—a stout bacillus, growing on gelatin—was present in some of the cultures" (Chem. Soc. Journ., July 1891). In an exhaustive memoir, due reference to the above attempt of Mr. Warington's would, of course, have been made; but in the impressionist sketch, which is alone possible in a Friday evening discourse at the Royal Institution, I take it that a lecturer must be allowed to use his own discretion as to what does and what does not fit into the small frame of sixty minutes without laying himself open to the imputation of having unjustly neglected or emphasized the work of individual investigators. Mr. Warington's name is so indissolubly connected with the subject of nitrification that it is the more surprising to me that he should have taken exception to the passage in question of my lecture.

PERCY F. FRANKLAND.

University College, Dundee, June 21.

Protection against Rain in the Elder.

IT is quite possible that the mode in which the flowers of the elder protect themselves against the rain has been described before, though I do not recollect to have seen any account of it. I have been noticing the great contrast between the aspect of a large elder-tree in full blossom, visible from my study window, presented yesterday and to-day. To-day, which is warm and sunny, every inflorescence is in its normal position, with the flat surface nearly horizontal, so as to get as much sun as possible. Yesterday was cold and very wet, and in every one of the inflorescences the upper part of the stalk was so curved as to bring, as far as the foliage would permit, the surface of the inflorescence to an angle of very nearly 90° with the horizon, so that the rain ran off, and scarcely any of it reached the interior of the flowers.

June 24. **ALFRED W. BENNETT.**

THE TOTAL SOLAR ECLIPSE, APRIL 15–16, 1893.

THE total eclipse of the sun, which will take place during the month of April next year, will most probably be very widely observed, not only because the shadow of the moon passes over such a great stretch of land, but because the phenomenon occurs at the period when a sun-spot maximum is approaching, at which time, of course, the disturbed state of the atmosphere of the sun is on the increase. The maximum time of totality is also in this case considerable, amounting to as much as 4m. 46s.

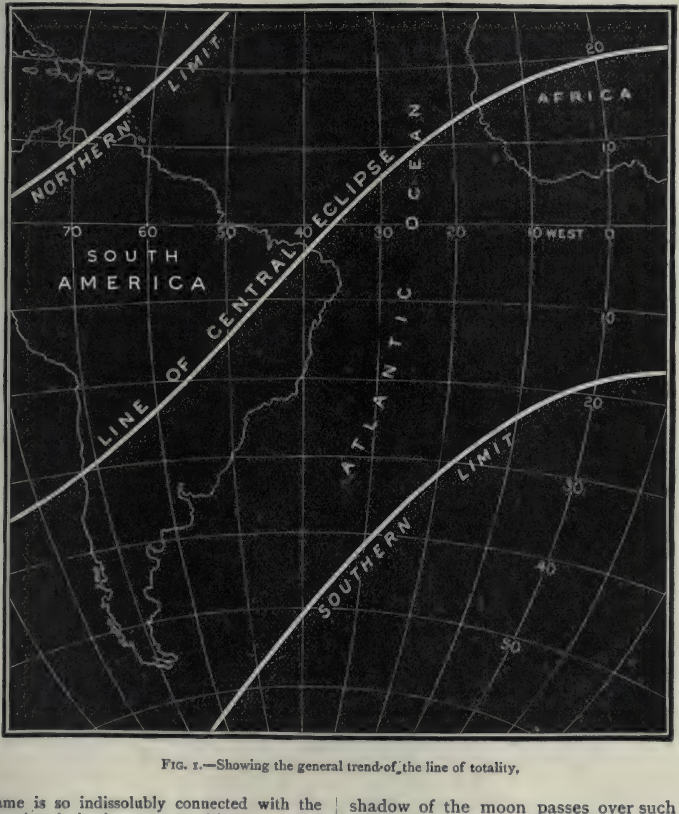

FIG. 1.—Showing the general trend of the line of totality.

Path of Shadow.—The general trend of the path of the shadow will be gathered from the accompanying diagram (Fig. 1). This track cuts through Chili, passes to the north of the Argentine Republic, skirts the provinces of Bolivia and Paraguay, and runs through the heart of Brazil. The centre of the shadow leaves South America near the town of Ceara or Fortaleza, and travels across the Atlantic Ocean, striking the African coast between Cape Verde and Bathurst.

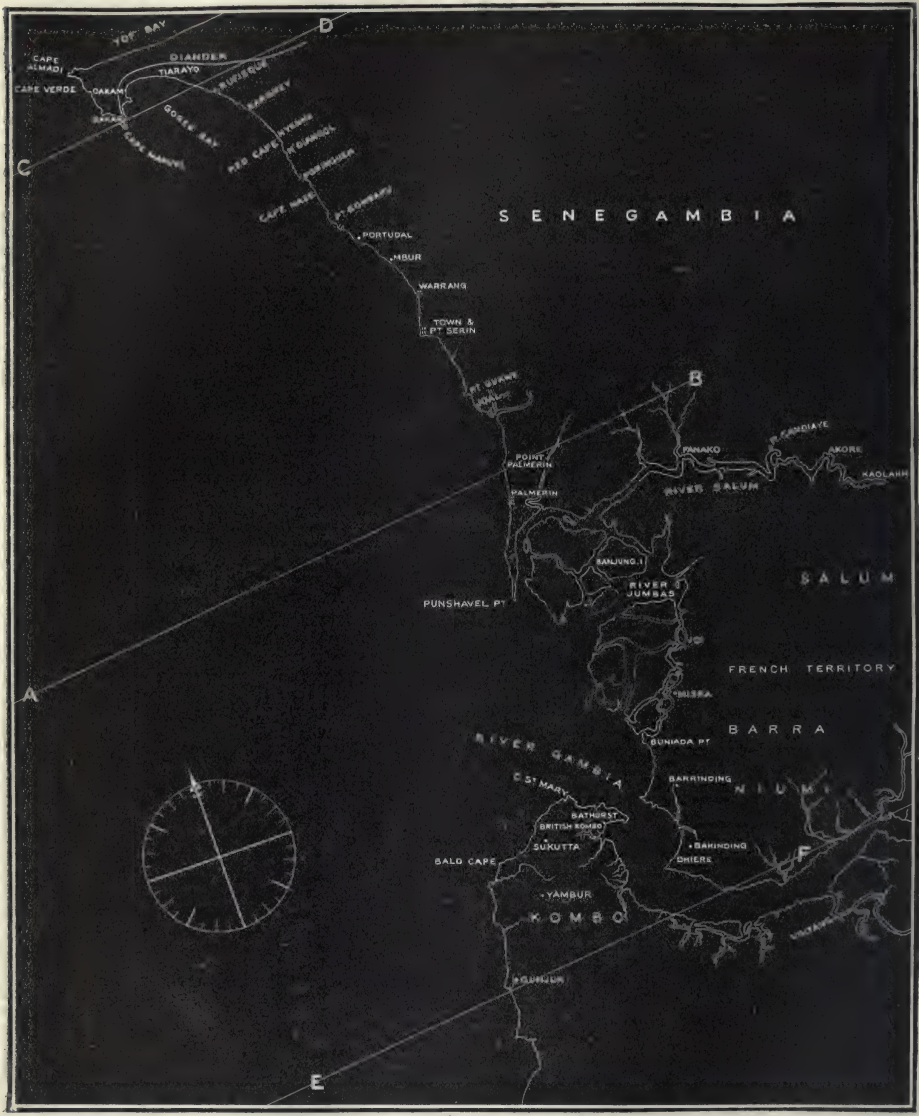

Fig. 2.—Showing the region on the West Coast of Africa over which the line of totality passes.

Probable Points for Observations.—The special points for observations may be said roughly to be three, viz. the region about Chili, the north-east corner of Brazil, *i.e.* the region of Ceara, and the Senegambian coast. These localities are so situated on the line of central and total eclipse that photographs of the corona taken at Chili will precede those taken in Africa by about $3\frac{1}{2}$ hours; while those obtained in the north-east of Brazil will be intermediate between the two.

Let us deal first with the Chilian district; this, we learn, will be occupied by the American astronomers. So far as we know at present, the Lick Observatory will send a party to Chili under the direction of M. Schaeberle, while Prof. Pickering will also direct other observers somewhere about the same spot. To the north of the Argentine Republic, and on the railway which runs up from Buenos Ayres, there seems to be another spot which would be available. This place, Rosario de la Frontera, lies to the north of Tucaman, and to the south of Jujuy, its approximate position being longitude 65° 7′, latitude 25° 48′ S. The duration of totality here amounts to 3m. 8s., the local time of its commencement being April 15, 20h. 40m. This place should, if possible, be made use of, for, besides being easily accessible, the probabilities from all accounts seem to be in favour of fine weather. From observations gathered from the nearest meteorological station, Salta, the mean annual temperature is found to be 63°·6 F., and the rainfall 22·8 inches; the chances for clear weather at this season being estimated at two-thirds.[1]

Following the track of the shadow across Brazil, no suitable spots are reached until the coast is approached; the most favourable place here is no doubt Fortaleza or Ceara, the capital of the province of Ceara, and a city of 20,000 inhabitants. Para Curù is also another very favourable point, lying nearly in the centre of the line of central eclipse; its position is longitude 38° 30′, latitude 3° 42′ S., and the local time of the beginning of the eclipse is April 15, 23h. 40m., the time of its duration being 4m. 44s.

With regard to the weather in this neighbourhood, the chances for clear skies seem, unfortunately, very small. The rainfall is reckoned as over 100 inches per annum, while even in April 10 inches has been usually recorded. For the last five years fifteen days on an average in this month have been rainy, the number in one year reaching twenty-one.

Taking into account the easy accessibility of the place, and its important position on the line of totality, it seems desirable that at any rate there should be some observers there.

Following the shadow over the Atlantic Ocean, we arrive at the shores of West Africa, on which probably both French and English expeditions will take up their respective positions. The accompanying map (Fig. 2) shows the coast-line of this region; AB, CD, and EF indicating the line of central eclipse and the northern and southern limits. The places which seem at present to be the most favourable are Joal and Palmerin, on the coast, if observations there are more convenient than others made inland.

The prospect of fine weather seems to be more probable here than in America. December, January, and February are the cloudy months, the weather during March and April being usually fine; the rains begin about May: sometimes tornadoes occur at intervals of five or six days, being accompanied by heavy rain, lasting generally from one to two hours, leaving the atmosphere afterwards bright and clear. The wind called the "Harmattan" during the first three months of the year is generally from the north-east and dry. It comes from the Sahara Desert, and brings with it consequently minute particles of sand, tending to give the atmosphere a yellowish tint. In April the prevailing wind is westerly to north-westerly, and not usually very strong.

The route which the English expedition will take has up the present not been definitely settled. Several lines of steamers run to Teneriffe and Grand Canary, and if one of Her Majesty's ships picked the expedition up at Teneriffe and carried them either to Bathurst or directly to the Salum River, the matter would be simplified; but failing this the only available route seems to be that by the British and African Steam Navigation Company. These steamers, touching at Madeira, Teneriffe, Grand Canary, Goree, and Dakar, naturally require much time to get to Bathurst. Of the return conditions it seems impossible to get any information at present.

Taking into account the accessibility and proximity to the line of totality, perhaps Palmerin and other places on the same river (River Salum) offer the greatest advantages. The bar at the mouth of the river would prevent a man-of-war of deep draft from proceeding up the river. As the region here is all under French protection, the necessary official letters will of course have to be obtained.

There are one or two other points relating to this region if it should by any chance be ultimately settled upon. Luxuries in the way of tea, sugar, milk (condensed), cocoa and milk, condiments, wine or spirits, flour, biscuits, soups, and preserved meats, should all be brought from England; rice, fowls, sheep, goats, and bullocks being always procurable from the native villages.

Cement and lime should also be taken out, and it seems probable that the huts for the instruments should be constructed at home and carried out there in pieces. The necessary housing of the observers (and escort, if any) would not prove very difficult, for either room could be found in the villages, or bamboo and grass huts could be quickly run up by the natives; it might be advisable to take one or two small tents, as they might prove very serviceable just after landing.

With regard to the packing of the necessary instruments, it may be said that the carriers' loads vary from 40 to 65 pounds; a case capable of being slung on a bamboo can weigh as much as 250 pounds, while to carry a weight of one hundredweight the services of two men would be required. Their wages would, of course, depend on whether they were obtained from Bathurst or the trading wharf on the river at the point of disembarkation, as in the latter case they could be discharged as soon as the selected spot had been reached.

UNIVERSITY OF DUBLIN: TERCENTENARY CELEBRATION.

THE celebration of the tercentenary of the University of Dublin will begin on Tuesday next, and all the necessary arrangements have now been made. Neither the Great College Hall nor the Chapel have been found large enough to hold the number of guests who have accepted the invitation of the Chancellor of the University (Earl of Rosse) and the Provost of Trinity College (Rev. Dr. Salmon), and it has been deemed necessary to hold the Commemoration Service in the Collegiate and Cathedral Church of St. Patrick, and the ceremony of the presentation of addresses in the Leinster Hall, the largest covered area in Dublin. In this hall the College banquet will be given, and the students have also engaged it for a University ball, which is to bring the festivities to a close.

It is expected and hoped that most of the invited guests and delegates will arrive in Dublin in the course of Monday evening, July 4, as the reception by the Provost of Trinity College will be held at 10 o'clock on the Tuesday morning, and immediately after this ceremony the members of the three classes of University officers with the members of the Senate, the other graduates and the undergraduates, will accompany the guests and delegates from the Examination Hall of Trinity College to St. Patrick's Cathedral, a distance of about a mile. Should the weather be fine and the procession properly marshalled, the general effect promises to be as fine as it will in the streets of Dublin be novel.

---

[1] The information for the most part concerning the American stations is gathered from Mr. H. S. Pritchett's article, "The Total Solar Eclipse April 15–16, 1·93," in the June number of *Astronomy and Astro-Physics*.

In the afternoon of the same day there will be a garden party in the College Park, to which upwards of three thousand persons have been invited, and the day will close with the performance by the members of the University Choral Society of an ode written by G. F. Savage-Armstrong, and set to music by Prof. Sir Robert Stewart, and by the civic ball.

On the Wednesday morning there will be a special Commencements for the conferring of honorary degrees. The Grace has already passed the Senate for eighty-three degrees, being a number equal to one-third of the total number of the expected guests and delegates. Among those on whom the degree of Doctor of Letters is to be conferred is Prof. Max Müller. The following will receive the degree of Master of Engineering: Lord Armstrong, Sir Benjamin Baker, Sir Isaac Lowthian Bell, Sir Charles William Wilson. The degree of Doctor of Sciences will be conferred on Prof. J. Burdon-Sanderson, Prof. Michael Foster, Prof. Ludimar Hermann, Sir George Murray Humphry, Prof. Julius Kollmann, Prof. Alexander Macalister, Prof. Richet, Prof. Sir William Turner, Wilhelm Waldeyer, Rev. Prof. Thomas George Bonney, Rev. William Henry Dallinger, Sir Archibald Geikie, Othniel Caleb Marsh, Baron Adolf Eric Nordenskiöld, Abbé Alphonse François Renard, John Hall Gladstone, George Downing Liveing, Lord Rayleigh, Prof. Joseph John Thomson, Prof. Thomas Edward Thorpe, Prof. William Augustus Tilden, Francesco Brioschi, Prof. Luigi Cremona, James Whitbread Lee Glaisher, Paul A. Gordan, Edward John Routh, George H. Darwin, Simon Newcomb, Isaac Roberts, F. Tisserand. The following are those who have been selected for the degree of Doctor of Medicine: H.R.H. Duke Charles of Bavaria, John Shaw Billings, Thomas Bryant, Sir Andrew Clark, Adolf Gusserow, Jonathan Hutchinson, Prof. Thomas Grainger Stewart. On the same day there will be a garden party at the Viceregal Lodge in Phœnix Park, given by His Excellency the Lord-Lieutenant and Lady Zetland, and in the evening the College banquet will be held in the Leinster Hall. Five hundred, including all the guests and delegates, have been invited.

Thursday, July 7, there will, in the morning, be a procession, from the Examination Hall of Trinity College to the Leinster Hall, of the College authorities and the delegates and others, to witness the presentation of addresses to the University by the delegates. A delegate from each country will make a short address, and the following have been invited to take their share in this interesting ceremony:—

Great Britain, her Colonies and Dependencies.—Sir James Paget, Bart., F.R.S.
America.—Prof. O. C. Marsh, of Yale University.
Austria-Hungary.—Prof. A. Vámbéry, of Buda-Pesth.
Belgium.—Prof. V. D'Hondt, of Ghent.
Denmark.—Prof. M. H. Saxtorph, of Copenhagen.
France.—Prof. Lannelongue, of Paris.
Germany.—Baron Ferdinand von Richthofen, of Berlin.
Holland.—Prof. Tiele, of Leyden.
Italy.—Prof. Gaudenzi, of Bologna.
Norway.—Prof. Hagerup, of Christiania.
Russia.—Prof. Wedenski, of St. Petersburg.
Switzerland.—Prof. Kollmann, of Basle.
Cambridge.—Dr. Peile, Vice-Chancellor.
Oxford.—Rev. Dr. Boyd, Vice-Chancellor.

On the evening of this day there will be a dramatic performance by the students of the College, the piece selected being Brinsley Sheridan's comedy, "The Rivals." In the afternoon there will be a garden party at the Royal Hospital, Kilmainham, given by the Right Hon. the Commander of the Forces in Ireland and Lady Wolseley.

The ceremonies will be brought to a close on Friday, on which day the following have been asked to address the College students: Profs. W. Waldeyer, Berlin; F. Blass, Kiel; A. Vámbéry, Buda-Pesth; F. Max Müller, Oxford; L. Cremona, Rome; B. J. Stockvis, Amsterdam; Léon Say, Paris; and General F. A. Walker, Massachusetts. The Athletic Union will hold their annual sports in the College Park and the University ball will be given in the afternoon and evening of this day.

On Saturday, July 9, the Royal Society of Antiquaries of Ireland have organized an excursion to Kells, the many objects of great antiquarian interest of which can easily be inspected within the limits of a short day from Dublin; the excursionists will leave the Great Northern Railway Station at 9 o'clock a.m., and return by the train reaching Dublin by 5.30.

Every information can be obtained on writing to the Hon. Secretaries of the Tercentenary Committee, Trinity College, Dublin.

EXHIBITION AT NÜRNBERG BY THE GERMAN MATHEMATICAL ASSOCIATION.

THE following prospectus will show the scope and object of this Exhibition:—

Deutsche Mathematiker-Vereinigung.

München, Mai 1892.

From September 12 to 18, 1892, the meetings of the "Deutsche Mathematiker-Vereinigung" and of the "Gesellschaft deutscher Naturforscher und Aerzte" will be held at Nürnberg.

At the proposition of the "Mathematiker-Vereinigung" the arrangement for an exhibition of models, drawings, apparatus, and instruments used in pure and applied mathematics is proposed. The project has secured the support of the Royal Bavarian Government.

The undertaking already enjoys the co-operation of a number of competent men of science, of several mathematical institutes of our colleges, besides that of various prominent publishers and well-known technical establishments, and thus we may hope that the exhibition will answer the expectations of its founders, viz.:

To open to wider spheres the various auxiliaries used in the instruction and investigation of both pure and applied mathematics in the shape of models, apparatus, and instruments and to forward the interests of this kind of scientific work.

At the request of the committee of the Mathematiker-Vereinigung I have the honour to invite you to participate in the exhibition, and to recommend to your special attention the following directions:—

I. Die mathematische Ausstellung gelegentlich der Versammlungen der "Deutschen Mathematiker-Vereinigung" und der "Gesellschaft deutscher Naturforscher und Aerzte" in Nürnberg will last from September 10 to 18, 1892. It comprises mathematical models, drawings, apparatus, and instruments serving both for teaching and research in pure and applied mathematics.[1]

II. The local committee of the Gesellschaft deutscher Naturforscher und Aerzte resp. the direction of the Bayerische Gewerbemuseum attends to the gratuitous granting of space required by the exhibitors.

III. The Deutsche Mathematiker-Vereinigung takes charge of all furniture, tables, screens, &c., attends to the opening and packing, also for supervision and care during the exhibition and for the insurance against fire. But assumes no responsibility either for damage or for loss of articles.

---

[1] In what belongs to the applications, we include only those having principally a mathematical interest. Concerning the experimental part of physics and those instruments, &c., which are of more practical use, it should be mentioned that all those more practical than theoretical relations will be displayed in a second exhibition, separate from ours, which comprises likewise the other branches of natural philosophy and the medicine.

That exhibition, entitled "Fachtechnische Ausstellung," under the authority of the "Gesellschaft deutscher Naturforscher und Aerzte" is arranged by the "Bayerischen Gewerbemuseum in Nürnberg," under the direction of Mr. Th. von Kramer, who has issued special programmes for that exhibition, and from whom further information may be obtained.

IV. Those who desire to exhibit under closed cases must do so at their own expense.

V. The charge of transport (to Nürnberg) and, if desired, the insurance of transport is at the expense of the exhibitor. In what refers to the return transport, by the courtesy of the directors of the Bavarian and the other main lines of German railways free transport is guaranteed for all unsold objects of the exhibition. All expense of home-transport beyond this border is at the expense of the exhibitor.

VI. An explanatory detailed catalogue of the mathematical exhibition is to be issued.

The first part will consist of essays, having reference to problems, results, and methods of geometrical representation.

The second part of an enumeration of all articles exhibited in connection with detailed theoretical descriptions. Here, if desired, the prices may be added. This part of the catalogue will be fully illustrated to give a vivid impression of the exhibited articles. We respectfully request all institutes, publishers, &c., to forward woodcuts, *clichés*, &c., which may be inserted in the text.

An appendix to the catalogue will be published, including all advertisements which may hereafter serve as a directory for all those interested.[1]

VII. As far as possible all technical explanations of the articles will be undertaken by the committee.

VIII. The committee will attend to all sales and buyings (which are in view by various mathematical institutes of our Hochschulen) and give all desired information.

During the exhibition the sold articles must not be removed from the exhibition rooms, except with special permission of the committee.

IX. The intention to participate in the exhibition may be given by the use of the "Exhibition Announcement" until July 1. Address: Herrn Prof. Dr. Walther Dyck, München, Hildegardstrasse 1½.

At the same time all papers and scientific notices for the catalogue respecting woodcuts and *clichés* for illustration must be sent to the same address.[2]

The editors reserve the right of all abbreviation and change in the notes of Part 2 of the catalogue that the uniformity may require.

X. All articles proposed for exhibition must be forwarded from September 1 to 7, under the address: Mathematische Ausstelluug in Nürnberg (Bayern), zu Handen der Herren Danler and Co.

The return of all articles will be effected within two weeks after the close of the exhibition under the conditions fixed above (No. V.)

XI. For nearer information in respect to the intentions and the extent of the exhibition we annex a preliminary classification of the articles.

1. *Geometry. Theory of Functions.*

Models employed in elementary teaching of geometry (solid geometry, trigonometry, descriptive geometry).

Polyhedra. Division of surfaces and spaces in polygons respecting polyhedra.

Plane curves.
Curves in space. Developable surfaces.
Surfaces of the second order.
Higher algebraic surfaces.
Transcendental surfaces.
Models illustrating geometry of complexes.
,, ,, curvature of surfaces.
,, ,, theory of functions.
,, ,, analysis situs.

2. *Arithmetic, Algebra, Integral Calculus.*

Calculating machines. Slide rules.

Instruments for solving equations and for construction of functional relations.

Curvometers, planimeters, integrating machines, instruments for solving differential equations.

3. *Mechanics. Mathematical Physics.*

Models employed in elementary teaching.

Kinematics. Machines for description and transformation of curves and surfaces. Pantographs, perspectographs.

Apparatus for demonstration of mechanical principles.

Equilibrium and motion of a point.

Poinsot motion of a rigid body; precession, nutation; dynamical tops, gyroscopes.

Models and articles showing the effect of stress flexion and torsion of solids.

Elastic properties of solids (especially of crystals).

Hydrodynamics.

Geometrical representations and mechanical apparatus illustrating physical phenomena (for ex. vibrations, wave-motion, propagation of sound and light. Thermodynamic and electrodynamic phenomena).

XII. It is understood that the exhibitors declare their willingness to submit to the present rules and further dispositions ordered by the committee for the interest of the exhibition.

For all further information please address the undersigned delegate of the committee.

Prof. Dr. Walther Dyck,
München, Hildegardestrasse 1½.

For the purpose of collecting and forwarding objects of interest, a Committee has been formed consisting of Lord Kelvin (Chairman), Lord Rayleigh, Profs. Sylvester, O. J. Lodge, G. F. Fitzgerald, W. G. Adams, Sir R. Ball, A. A. Common. Secretaries: A. G. Greenhill, O. Henrici.

The Secretaries will forward prospectuses and forms of application to intending exhibitors, and will take charge of objects at the Central Institution, Exhibition Road, South Kensington, S.W., and forward the objects at the proper time to Nürnberg, unless forwarded direct by the exhibitors.

THE KEKULÉ FESTIVAL AT BONN.

On June 1 a remarkable demonstration took place at the University of Bonn. The occasion was the twenty-fifth anniversary of the call of August Kekulé to the Professorship of Chemistry at that University. The details, which we have taken chiefly from the *Kölnische Zeitung*, will be of interest to the student of chemistry, and probably of value to the future historian of the science.

The ceremony began in the morning with an enthusiastic ovation on the part of the students. The chemical theatre was decorated with plants; on the blackboard figured the benzene hexagon, made up with garlands of flowers, in the midst of which appeared the letters A. K. as a monogram of roses. At the usual lecture hour Prof. Kekulé entered, and was greeted with great enthusiasm. One of the chemical students, Alfred Helle, delivered a graceful address, in which he congratulated his fellows on being privileged to sit at the feet of the greatest of living chemists, ending by calling for three cheers for the Professor, in which the audience heartily joined.

Prof. Kekulé then addressed the students, detailing with characteristic humour some passages in his life. He was, he said, a pupil at the Darmstadt Gymnasium, where he chiefly devoted himself to mathematics. He was destined by his father for the profession of architect, and some houses still existed in Darmstadt, the plans of which he had drawn when a youth at the Gymnasium. At Giessen, where he went to study architecture, he attended Liebig's lectures, whereby he was enticed to chemistry. But his relations would not at first hear of his changing his profession, and he was given half a year's grace to think over it. He spent this time at the Polytechnicum at Darmstadt; from which circumstance arose the myth, affirmed by Kolbe, that he was a "Realschüler," and not, as was really the case, a "Gymnasiast." His first teacher in chemistry at Darmstadt was Moldenhauer, the inventor of lucifer matches. His leisure time was spent in modelling in plaster and at the lathe. He was then permitted to return to Giessen. "I attended," he said, "the lectures, first of Will and then of Liebig. Liebig was at work on a new edition of his 'Letters on Chemistry,' for which many experiments had to be carried on. I had to make estimations of ash of albumen, to investigate gluten in plants, &c. The names of the young chemists who helped Liebig were mentioned in the book, among them mine. The proposal was then made to me, just at the time when Liebig intended to make me his assistant, that I should go for a year abroad, either to Berlin, which at that time was to Giessen a foreign land, or to Paris. 'Go,' said Liebig, 'to Paris: there your views will be widened; you will learn a new language; you will get acquainted with the life of a great city; but you will not learn chemistry there.' In that, however, Liebig was wrong. I attended lectures by Fremy, Wurtz, Pouillet, Regnault; by Marchandis on physiology, and by Payen on technology. One day, as I was sauntering along the streets, my eyes encountered a large poster with the words 'Leçons de philosophie chimique, par Charles Gerhardt, ex-Professeur de Montpellier.' Gerhardt had resigned his Professorship at Montpellier, and was teaching philosophy and chemistry as *privatdocent* in Paris. That attracted me, and I entered my name on the list. Some days later I received a card from Gerhardt; he had seen my name in Liebig's 'Letters on Chemistry.' On my calling upon him he received me with great kindness, and made me the offer, which I could not accept, that I should become his assistant. My visit took place at noon, and I did not leave his house till midnight, after a long talk on chemistry. These discussions continued between us at least twice a week, for over a year. Then I received an offer of the post of assistant to Von Plantu, at the Castle of Reichenau, near Chur, which I accepted, contrary to Liebig's wish, who recommended me as assistant to Fehling at Stuttgart. So I went to Switzerland, where I had leisure to digest what I had learnt in Paris during my intercourse with Gerhardt. Then I received an invitation from Stenhouse, in London, to become his assistant, an invitation I was loth to accept, since I regarded him, if I may be allowed the expression, as a 'Schmierchemiker." By chance, however, Bunsen came to Chur on a visit to his brother-in-law, at whose house I first met him. I consulted Bunsen as to Stenhouse's offer, and he advised me by all means to accept it. I should learn a new language, but I should not learn chemistry. So I came to London, where as Stenhouse's assistant I did not profit much. By means of a friend, however, I became acquainted with Williamson. The latter had just published his ether theory, and was at work on the polybasic acids (in particular on the action of PCl_5 on H_2SO_4). Chemistry was at one of its turning-points. The theory of polybasic radicals was being evolved: with Williamson was also associated Odling. Williamson insisted on plain simple formulæ without commas, without the buckles of Kolbe, or the brackets of Gerhardt. It was a capital school to encourage independent thought. The wish was expressed that I should stay in England and become technologist, but I was too much attached to home. I wished to teach in a German University. But where? In order to get acquainted with the circumstances at the several Universities, I became a travelling student. In this capacity I came, among other Universities, to Bonn. Here there was no chemist of eminence, and hence there were no prospects. Nowhere did there seem so much promise and so great a future as at Heidelberg. I could ask no help of Bunsen. 'I can do nothing for you,' he said, 'at least not openly. I will not stand in your way, but more I cannot promise.' I fitted up a small private laboratory in the principal street in Heidelberg at the house of a corn merchant, Gross by name—a single room with an adjoining kitchen. I took a few pupils, among whom was Baeyer. In our little kitchen I finished my work on fulminate of silver, while Baeyer carried out his researches, which subsequently became famous, on cacodyl. That the walls were coated thick with arsenious acid, and that silver fulminate is explosive, we took no thought about. After two years and a half I received a call to Ghent as ordinary professor. There I stayed nine years, and had to lecture in French. With me to Ghent came Baeyer. Through the kindness of the then Prime Minister of Belgium, Rogier, I obtained the means to establish a small laboratory. I had there with me a number chiefly of more advanced students, among whom I may name Baeyer, Hübner, Ladenburg, Wichelhaus, Linnemann, Radzizewski, and Meyer. There was not so much a systematic course of instruction as a free and pleasant academic intercourse. After nine years' work, I received the call to Bonn." With some account of his work in Bonn, and with a reference to the great attention he had always received from his pupils, Prof. Kekulé concluded his address. The enthusiasm it occasioned, says the *Kölnische Zeitung*, baffled description.

---

[1] The fees for insertion in the appendix are 30 Reichsmark for the whole page (great 8°), 18 R.-M. for ½ page, 10 R.-M. for ¼ page, 5 R.-M. for ⅛ page.

[2] All advertisements for the Appendix and payments for same must not be deferred later than August 1, to the same address, Prof. Dyck.

The Professor then received the congratulations of his personal staff, as well as those of the University officials, among whom were the Rector Prof. Strasburger, the Curator Dr. Gandtner, and the Dean of the Philosophical Faculty Prof. Schlüter. In the evening the Bonn students honoured him with a torchlight procession, it being the third time the Professor had received this, the most conspicuous honour which is bestowed by German students. The first occasion was in 1875, when he declined the Professorship at Munich. The second was in 1878, when he was Rector of the University, held to commemorate the restoration of unity among the students after a long period of disunion. Among the torch-bearers on that occasion was the present Emperor of Germany.

In addressing the students, Prof. Kekulé reminded them of the previous occasions on which they had honoured him in like manner, and impressed on them the necessity of guarding and fostering the unity they had attained. Thus ended an impressive and memorable incident in the history of chemical science.

J. E. MARSH.

THE TRUE BASIS OF ANTHROPOLOGY.[1]

THE Nestor of American philologists, and at the same time the indefatigable Ulysses of comparative philology in that country, Mr. Horatio Hale, has just published in the Transactions of the Royal Society of Canada, an important essay on "Language as a Test of Mental Capacity," being an attempt to demonstrate the true basis of anthropology. His first important contribution to the science of language dates back as far as 1838–42, when he acted as ethnographer to the United States Exploring Expedition, and published the results of his observations in a valuable and now very scarce volume, "Ethnography and Philology." He has since left the United States and settled in Canada. All his contributions to American ethnology and philology have been distinguished by their originality, accuracy, and trustworthiness. Every one of them marks a substantial addition to our knowledge, and, in spite of the hackneyed disapproval with which reviewers receive reprints of essays published in periodicals, it is much to be regretted that his essays have never been published in a collected form.

---

[1] "Language as a Test of Mental Capacity." By Horatio Hale. From the Transactions of the Royal Society of Canada, 1891.

Mr. Horatio Hale's object in the essay before us is to show that language separates man from all other animals by a line as distinct as that which separates a tree from a stone, or a stone from a star.

"A treatise," he writes, "which should undertake to show how inanimate matter became a plant or an animal, would, of course, possess great interest for biologists, but it would not be accepted by them as a treatise on biology. In like manner a work displaying the anatomy of man in comparison with that of other animals cannot but be of great value, and a treatise showing how the human frame was probably developed from that of a lower animal must be of extreme interest; but these would be works, not of anthropology, but of physiology or biology. Anthropology begins where mere brute life gives way to something widely different and indefinitely higher. It begins with that endowment which characterizes man, and distinguishes him from all other creatures. The real basis of the science of anthropology is found in articulate speech, with all that it indicates and embodies." He does not hesitate to maintain that solely by their languages can the tribes of men be scientifically classified, their affiliations discovered, and their mental qualities discerned. These premises, he says, compel us to the logical conclusion that linguistic anthropology is the only "Science of Man."

These words explain at once the whole character of this important essay. Mr. Horatio Hale is a great admirer of Darwin, but not of the Darwinians. He contrasts Darwin's discernment of the value of language with the blindness of his followers, who are physiologists and nothing else. Why anthropology has of late been swamped by physiology, Mr. Horatio Hale explains by the fact that the pursuit of the latter science is so infinitely the easier. "To measure human bodies and human bones, to compute the comparative number of blue eyes and black eyes in any community, to determine whether the section of a human hair is circular, or oval, or oblong, to study and compare the habits of various tribes of man, as we would study and compare the habits of beavers and bees, these are tasks which are comparatively simple. But the patient toil and protracted mental exertion required to penetrate into the mysteries of a strange language, and to acquire a knowledge profound enough to afford the means of determining the intellectual endowments of the people who speak it, are such as very few men of science have been willing to undergo." Mr. Horatio Hale has a right to speak with authority on this point, for, besides having studied the several languages of North America, of Australia and Polynesia, no one has more carefully measured skulls, registered eyes, measured hair, and collected antiquities and curiosities of all kinds than he has done during his long and busy life. His knowledge of the customs of uncivilized races is very considerable. No one knows the Indian tribes and likewise the Australians better than he does, and he is in consequence very severe on mere theorizers who imagine they have proved how the primitive hordes of human beings, after herding together like cattle, emerged slowly through wife-capture, mother-right, father-right, endogamy, exogamy, totemism, fetichism, and clan systems, to what may be called a social status. He holds with Darwin that man was from the beginning a pairing animal, and that the peculiar usages of barbarous tribes are simply the efforts of men, pressed down by hard conditions, below the natural stage, to keep themselves from sinking lower. He gives a most graphic description of changes of civilization produced by change of surroundings in the case of the savage Athapascans, and their descendants, the quick-witted and inventive Navajos. He holds that the inhabitants of Australia were originally Dravidians, and that their social and linguistic deterioration is due to the miserable character of the island in which they had taken refuge, possibly from the Aryans, when pressing upon the aboriginal inhabitants of the Dekhan. He points out a few grammatical terminations in the Dravidian languages which show some similarity to the terminations of Australian dialects. The dative, for instance, is formed in the Dravidian Tulu by *ku*, and in the Lake Macquarie and Wiradhurei dialects of Australia by *ko*. In both families the *k* of *ku* and *ko* is liable to be changed into *g*. The plural suffix in Tamil is *gal*, in Wiradhurei *galan*. Thus in Tamil *maram*, tree, forms the nom. plur. *marangal*, the dat. plur. *marangaluk-ku*; while in Wiradhurei, *bagai*, shell, appears in the nom. plur. as *bagaigalan*, in the dat. plur. as *bagaigalan-gu*. On this point, however, Mr. Horatio Hale ought to produce fuller evidence, particularly from numerals, and the common household words of uncivilized tribes. The pronouns show many coincidences with Dravidian and Australian languages. No one is better qualified for that task than he is, for we really owe to him the first trustworthy information about the Australian dialects. He considers all the dialects spoken in Australia as varieties of one original speech, and he has proved their wonderful structure by several specimens contained in his first book, published nearly fifty years ago, and again in this last essay of his.

There is no doubt that this essay will provoke much opposition, but no one can read it without deriving most valuable information from it, and without being impressed with the singularly clear and unbiassed judgment of the author. It is to be hoped that if there is any controversy it may be carried on in the same scientific and thoroughly gentlemanlike tone in which Mr. Horatio Hale deals with those whom he has to reprove. Thus, when Prof. Whitney, a fertile writer on linguistic science in America, commits himself to the statement that the Dravidian languages have "a general agglutinative structure *with prefixes only*," Mr. Horatio Hale good-naturedly remarks, "this is doubtless a misprint for *with suffixes only*." And when Prof. Gerland, in his continuation of Waitz's invaluable work "Die Anthropologie der Naturvölker," refers to Mr. Horatio Hale as describing the hair of the Australians as *long, fine, and woolly*, he points out that he, on the contrary, described their hair as neither woolly, like that of the Africans and Melanesians; nor frizzled, like that of the Feejeeans; nor coarse, stiff, and curling, as with the Malays; but as long, fine, and *wavy*, like that of Europeans. He naturally protests against Prof. Friedrich Müller charging him with having committed such a blunder, which, as he remarks, would be as bad as if he had described the Eskimos as having black skins. But there is not a single offensive expression in the whole of his essay, though the opportunities would have been many for adopting the style of hitting indiscriminately above and below the belt. Though he differs from Prof. Whitney, he evidently ranks him very high, and as second only to "that eminent Sanskrit scholar, Sir Monier Monier-Williams."

LEWIS MORRIS RUTHERFURD.

ON May 30 last there passed away from us one whose name was familiar to many, and who was respected and beloved by all who were fortunate enough to have made his acquaintance. By the death of Lewis Morris Rutherfurd, who died at the age of seventy-six, at his estate in Tranquillity, New Jersey, astronomical science especially suffers, for he was one of the pioneers of astronomical photography and spectroscopy, and the introducer of many of the practical methods which have opened to us such a vast field of research.

Born at Morrisania, New Jersey, on November 25, 1816, he first devoted himself to the study of law, but finding his mind bent more on astronomical pursuits, he soon thought fit to leave this profession, and being well equipped with the necessary private resources, he commenced in the year 1848 to erect an observatory in the city of New York at his own residence. On its completion, it was furnished with an 11¼-inch refractor, which he had made under his own personal direction by Fitz, and a transit instrument.

The first work he set himself to do related to the spectra of the stars. As soon as Kirchhoff's discovery was announced, Donati, at Florence, in 1860, made the first efforts in this direction; this was followed by other observers, among whom was Rutherfurd. In 1863 he published his first paper on the spectra of the celestial bodies, and indicated that the various stellar spectra which he had then observed were susceptible of being arranged in different groups. His paper, which was published in *Silliman's Journal*, vol. xxxv. p. 71, contained the following extract with reference to this classification:—"The star spectra present such varieties that it is difficult to point out any mode of classification. For the present, I divide them into three groups: First, those having many lines and bands, and mostly resembling the sun, viz. Capella, β Geminorum, α Orionis, &c. These are all reddish or golden stars. The second group, of which Sirius is the type, presents spectra wholly unlike that of the sun, and are white stars. The third group, comprising α Virginis, Rigel, &c., are also white stars, but show no lines; perhaps they contain no mineral substance, or are incandescent without flame."

Turning his attention to object-glasses for visual and photographic purposes, he described in 1865 a new form which he had specially designed for the latter. This, needless to say, brought about a great revolution in the processes employed. The history of his early attempts to produce photographically corrected object-glasses, and the wonderfully sharp and beautiful photographs of the moon which he finally obtained, will always be marked as an important era in the application of the camera to the equatorial telescope. The photographs taken at the present day, even although they are produced with larger lenses and with a more perfect knowledge of photographic processes, and with the advantages afforded by dry plates, excel only in a trifling degree those taken with the small Rutherfurd equatorial.

Another important piece of work, which occupied him some considerable time, was the mapping, by means of the photographic process, of star clusters and star groups. His ingenuity in devising and constructing accurate micrometers for measuring the impressions of the star clusters opened out a new method by which the proper motion of the stars could be photographically determined, and even their parallaxes, eliminating entirely the errors of observers.

It was absolutely essential, as he knew, in order to obtain a perfect method of measurement of the photographs, to attain the utmost perfection in the cutting of the threads of the micrometer screw, and some idea of the care which he bestowed on them may be gathered from the fact that he took three years to make a single screw. In order to test its quality, it struck him that it would be a happy thought to see if it would enable him to rule a grating. He accordingly set the apparatus up in his bedroom, and by means of an automatic arrangement kept it going all night, as at that time the local vibrations were fewest. The result was that he was able to make the most perfect gratings known, which are only now surpassed by those of Rowland, who followed in his wake.

The photographic corrector, which consisted of an additional lens to be applied to visual object-glasses, to render them fit for photographic use, was also due to his exceptional mechanical ability, and was brought out in the year 1868.

Owing to failing health he was at last obliged to give up all idea of making observations, so he resigned himself to a thorough supervision of the great number of measurements of the photographs of the star clusters that by this time had very considerably accumulated.

In the year 1884, Columbia College, New York, was the recipient of all his astronomical instruments, apparatus, and completed measures. It is only a fortnight ago when a notice of the measures of the Pleiades, which were prosecuted by Mr. Jacoby, under the direction of Prof. Rees, was made in these columns, and it will not be long before several other clusters will be published.

In this brief notice we have only referred to some of the more salient points with which he enriched the domain of astronomical science; and his was no mean spirit striving to confine to his own use the various methods of work and improvements he introduced: he scattered his gratings with a lavish hand among all who were likely to make any use of them, and his greatest delight was to help others occupied in researches kindred to his own.

NOTES.

Sir Archibald Geikie has been appointed by the Council of the Royal Society to be one of the Governors of Harrow School.

It was with deep regret that we saw the announcement in Monday's *Times* of the death of Admiral Mouchez, the Director of the Paris Observatory. In him France has lost one of her most active men of science, whose place it will be no easy task to fill.

At St. John's College, Cambridge, on July 9, at 2.30 p.m., there will be held a meeting of the General Committee that was formed for placing a suitable memorial of the late Prof. Adams in Westminster Abbey. This meeting is specially called to consider a modification in the form of the memorial. The resolution, as passed in February, was to the effect that the memorial should "consist of a bust with tablet and inscription," but as the Dean has been unable to sanction any site in that part of the Abbey in which it was first proposed to be placed, but has offered an excellent position for a medallion, near the monument of Newton and the grave of Sir John Herschel, and close to the memorials of Darwin and Joule, the Executive Committee recommend that this offer be accepted, and that the terms of the former resolution be altered to "That the memorial consist of a medallion and inscription."

The *Botanische Zeitung* publishes a programme of the International Botanical Congress to be held in Genoa. On Sunday evening, September 4, there will be a reception of the foreign botanists present. On Tuesday the Botanical Institute and Garden, presented to the Municipality of Genoa by Mr. Thos. Hanbury, will be formally opened. On Saturday, September 10, the Acclimatisation Garden of Mr. Hanbury at Mortola will be visited. The rest of the week will be occupied by scientific sittings, receptions, and excursions.

Dr. Benecke, the Director of the Experimental Station at Klaten, Java, has offered a prize of 1000 marks for the best essay, founded on original observations and experiments in cultivation, on the causes of the red colour in the fibrovascular bundles of *Sorghum*, which accompanies the disease known as "sereh." A very similar disease has recently become very destructive to the sugar-cane crop in Java.

In our account last week of the Ladies' *Conversazione* of the Royal Society we stated that the Telephone Company's installation was the means by which the music from the Paris opera was rendered audible. This, as we have reason now to know, was incorrect. The Post Office undertook the whole affair, no company having anything at all to do with it.

PROF. BURT G. WILDER, M.D., of Cornell University, sends us the following correction:—In a circular, "American Reports upon Anatomical Nomenclature," issued last winter by Prof. Wilder, as Secretary of the Committee of the Association of American Anatomists, in the third paragraph of the third page, the Chairman of the Committee of the Anatomische Gesellschaft should be Prof. A. von Kölliker, and the Chairman of the American division (appointed in 1891 by the American Association for the Advancement of Science) of the International Committee on Biological Nomenclature should be Prof. G. L. Goodale. Prof. Wilder desires to express his regret for the errors, due in the one case to his own misapprehension, and in the other to a clerical mistake.

UNDER the title of "The Cambridge Natural History," Messrs. Macmillan and Co. have in active preparation an important series of volumes on the Natural History of Vertebrate and Invertebrate Animals, edited, and for the most part written, by Cambridge men. While intended in the first instance for those who have not had any special scientific training, the volumes will, as far as possible, present the most modern results of scientific research. Thus the anatomical structure of each group, its development, palæontology, and geographical distribution, will be considered in conjunction with its external character. Care will, however, be taken to avoid technical language as far as possible, and to exclude abstruse details which would lead to confusion rather than to instruction. The series will be under the general editorship of Mr. J. W. Clark, the University Registrar, and Mr. S. F. Harmer, Superintendent of the Museum of Zoology. The following writers are engaged upon the groups which precede their names:—*Mammals*, Mr. J. J. Lister; *Birds*, Mr. A. H. Evans; *Reptiles* and *Amphibia*, Dr. Gadow, F.R.S.; *Fish*, Mr. W. Bateson; *Mollusca*, Mr. A. H. Cooke; *Polyzoa*, Mr. S. F. Harmer; *Brachiopoda*, Mr. A. E. Shipley; *Insects*, Mr. David Sharp, F.R.S.; *Myriapoda*, Mr. F. G. Sinclair; *Arachnoida*, Mr. C. Warburton; *Crustacea*, Prof. W. F. R. Weldon; *Cœlenterata*, Mr. S. J. Hickson; and *Sponges*, Dr. W. J. Sollas. It is hoped that some of the volumes which are already far advanced may appear in the course of next year. The series will be fully illustrated.

THE weather during the past week has been unsettled, but considerably warmer generally. Towards the close of last week solar halos were visible in the south, and a depression moved along our west coasts in a north-north-easterly direction, accompanied by showers, while the daily temperatures reached upwards of 70° in the inland parts of England. At the beginning of the present week, a still further increase of temperature occurred, the maxima exceeding 80° in the midland and eastern parts of England, and fog became prevalent over the Channel and the southern parts of England. The atmospheric conditions, which during the greater part of the period were cyclonic, with moderate or strong south-westerly winds, amounting to a strong gale from the westward in Caithness on Monday, subsequently became anticyclonic with light north-easterly and easterly winds over England; but on Tuesday evening a depression lay over the mouth of the Channel, the conditions rapidly became more unsettled, and a very severe thunderstorm occurred on that night in London and the greater part of England, accompanied by heavy rain. The *Weekly Weather Report* for the period ending the 25th instant shows that the rainfall exceeded the mean in nearly all districts; in the eastern and southern parts of England the excess was rather large. But reckoning from the beginning of the year there was still a deficit in all districts, although the amount was trifling in the north-east and north-west of England.

A NEW meteorological journal, entitled *L'Atmosphère*, has recently appeared in Paris. It contains several short original articles and miscellaneous notes collected by the director of a private observatory, named Tour Saint-Jacques. At present there is no such journal published in France, excepting the *Annuaire* of the Meteorological Society, containing the papers read by its members. The current number (No. 5) contains an article on the optical phenomena of the atmosphere, by A. Cornu, member of the Institute, and one on solar phenomena and terrestrial magnetism, by E. Marchand, of the Lyons Observatory. It also gives a list of the principal meteorological papers published in recent serials.

A SERIES of severe earthquake shocks is reported from Guodolajara, Mexico. The first shock was felt last Friday night, and lasted eighteen seconds. Windows were broken and plastering cracked in numerous houses, and hundreds of panic-stricken people took refuge in the streets until daylight. On Saturday a second shock occurred, wrecking a number of buildings. Several persons were seriously hurt, but in no case are their injuries expected to prove fatal. Several other shocks have been felt since. The volcano Colima is said to be in a state of much activity. Great volumes of sulphur, smoke, and lava are issuing from the crater.

A PAPER setting forth a proposal for a national photographic record and survey, by Mr. W. J. Harrison, was lately read before the Photographic Society of Great Britain, and has now been issued separately. Mr. Harrison's idea is that a pictorial record of the present condition of the country should be secured by photography, the work being accomplished by professionals, individuals (amateurs), photographic societies, and agencies under the control of the Government. In the course of the paper he gives an interesting account of the way in which the local photo-survey of Warwickshire is being carried out.

ANTHROPOLOGISTS will read with interest some folk-songs and myths from Samoa, printed in the new number of the Journal and Proceedings of the Royal Society of New South Wales (vol. xxv.). They are translated by the Rev. G. Pratt, and introductions and notes are provided by Dr. John Fraser.

PROF. F. STARR will contribute to the July number of the *Popular Science Monthly* an article on "Anthropological Work in America." It will be accompanied by portraits of seventeen American anthropologists. According to *Science*, the article shows that "both in quality and amount, the work of Americans in this field compares favourably with that of Europeans."

A SOCIETY which may have opportunities of doing much valuable work has been formed in Wellington, New Zealand. It is called the Polynesian Society, "Polynesia" being intended to include Australia, New Zealand, Melanesia, Micronesia, and Malaysia, as well as Polynesia proper. The President is Mr. H. G. Seth-Smith, chief judge of the native land court, while the Queen of Hawaii is patron. We have just received the first number of the Society's Journal, in which there are papers on the races of the Philippines, by Elsdon Best; Maori deities, by W. L. Gudgeon; the Tahitian "Hymn of Creation," by S. P. Smith; Futuna, or Horne Island, and its people, by S. P. Smith; Polynesian causatives, by E. T.; and the Polynesian bow, by E. Tregear. There is also a paper giving the genealogy of one of the chieftainesses of Rarotonga, by a native of Rarotonga. The original was written in 1857, and is printed in the Journal, with a translation by Mr. Henry Nicholas, and notes by the editors. The editors are of opinion that the paper "apparently supports by direct traditional testimony the theory propounded by Hale, and subsequently advocated by Fornander, of the occupation of the Fiji Group by the Polynesian race, and of their later migration eastward to Samoa and the Society Group."

THE facility with which enlargements can now be produced, and the introduction of good commercial bromide paper, to say nothing of the artistic effects of the results, have all tended to increase the popularity of the practice of enlarging. When an amateur was formerly in need of moderate-sized pictures, he was compelled more or less to use a large camera, but now the inclination is to employ small cameras and therefore small plates, and to subsequently adopt the enlarging process to give him the required size picture. A very useful and handy little book treating of this process, written by Mr. John A. Hodges, has lately been issued by Messrs. Iliffe and Son, and contains much practical information for working either by artificial light or daylight. Methods of constructing cameras suitable for this work, lanterns, and various accessories, are all very well described and illustrated, and if carefully followed out will render many an amateur independent of the instrument-maker. In the section relating to the chemical manipulations there are also some useful hints which will save a beginner much annoyance and help him to produce satisfactory results.

OBERLIN COLLEGE, Ohio, is issuing a series of Bulletins giving the results of special work done in its museum and laboratories. Two have now been published, the first being a preliminary list of the flowering and fern plants of Lorain County. The second, which we have just received, contains a descriptive list of the fishes of Lorain County, and has been prepared by Mr. L. M. McCormick.

ACCORDING to the *Pioneer Mail* of June 8, the residents of Howrah have been finding lately that jackals are animals of anything but an attractive temper. In some cases they have come right up to the bungalows in search of prey. A little girl, aged about five years, was playing in a verandah, when a jackal suddenly rushed on her, and was dragging her away, when she was rescued. She was severely bitten. Three natives, while walking along Kooroot Road, were attacked by a jackal, which was only driven off after a stubborn fight; and a tale is told of two women, while standing near a tank, being attacked and bitten. So serious has the state of matters become, that the public propose to submit a memorial to the district magistrate praying for the adoption of measures for the destruction of these pests.

REFERRING to Malta's spring visitors, the *Mediterranean Naturalist* for June says that during the preceding month the valleys and gorges were alive with orioles, warblers, rollers, and bee-eaters. In the rich crimson clover enormous numbers of quails found shelter during their sojourn *en route* for the Continent, while the branches and foliage of the carob, the prickly pear, and the orange trees were thronged with harriers and larks.

MR. F. TURNER contributes to the April number of the *Agricultural Gazette of New South Wales* a paper on the carob bean tree as one of the commercial plants suitable for cultivation in New South Wales. The Agricultural Department distributed a quantity of seed last year, and some healthy young plants raised from this seed are now growing in several parts of the colony. Mr. Turner expects that when the tree becomes better known to cultivators it will be extensively grown to provide food for stock, more especially during adverse seasons. The carob can not only be trained into a very ornamental shade tree, but may be planted as a wind-break to more tender vegetation. He advises all who cultivate it to keep bees, if only a single hive. It is astonishing, he says, how many flowers these industrious insects will visit in the course of a day, and be the agency whereby they are fertilized.

SOME time ago a sugar school was established in connection with the State University, Lincoln, Nebraska, and if we may judge from the first formal report, lately submitted by Prof. Lloyd, it is likely to do much excellent work. The school opened on January 5 with twenty-five students. These students were mostly members of other classes in the chemical department of the University; the only preparation required for entrance being a clear conception of the principles of elementary chemistry, such as may be obtained in some of the high schools of Nebraska. The course consisted of two lectures a week, given by Mr. Lyon, with five hours of laboratory work. The lectures embraced the following subjects: (1) chemistry of the sugars; (2) technology of beet-sugar manufacture; (3) culture of the sugar beet. During the latter part of the winter term, Prof. DeWitt B. Brace gave the class four lectures on the theory of light, dealing with (1) the wave theory of light; (2) polarization of light; (3) rotation of the plane of polarization; (4) application of these principles to the polariscope and to the different forms of saccharimeters. It is hoped that in the coming year the work may be greatly extended.

A "Dictionnaire de Chimie industrielle" is being issued in parts, under the direction of A. M. Villon, by the "Librairie Tignol." It gives an account of the applications of chemistry to metallurgy, agriculture, pharmacy, pyrotechnics, and the various arts and handicrafts.

MESSRS. LONGMANS, GREEN, AND CO. have issued a third edition, revised and enlarged, of Prof. E. A. Schäfer's "Essentials of Histology." The intention of the author is to supply students with directions for the microscopical examination of the tissues.

A WORK on the "Migration of Birds," by Charles Dixon, will shortly be published by Messrs. Chapman and Hall.

A PAPER upon the oxidation of nitrogen by means of electric sparks is contributed, by Dr. V. Lepel, to the current number of the *Annalen der Physik und Chemie*. It is well known that small quantities of nitric and nitrous acids and their ammonium salts are produced during the passage of high tension electrical discharges through moist air. Dr. V. Lepel's experiments have been conducted with the view of obtaining more precise information concerning the nature of the chemical reactions which occur, and the experimental conditions most favourable for increasing the amount of combination. The first action of the spark discharge appears to be the production of nitric oxide, which is immediately converted by the oxygen present into nitrogen peroxide. The latter then reacts with the aqueous vapour present, forming nitric acid and liberating nitric oxide in accordance with the well-known equation $3NO_2 + H_2O = 2HNO_3 + NO$. It has been found, however, that the continued passage of sparks through the same quantity of moist air does not result, as might at first sight be expected, in the conversion of more and more of the atmospheric gases into oxidized products. For the passage of sparks through the gaseous oxides of nitrogen first formed results in their decomposition again into their elementary constituents. If, for instance, spark discharges are passing at the rate of one per second, the whole of the nitrogen peroxide molecules have not time to react with the water molecules to form nitric acid, before the passage of the next spark, and hence some of them suffer decomposition; indeed, it is probable that a number of the nitric oxide molecules first formed have not even time to combine with oxygen to form the peroxide before the passage of the next discharge, which brings about their dissociation. Hence it is that, in a closed space, a limit is soon reached beyond which there is no further increase in the amount of nitric acid. For this reason the yield of nitric acid has hitherto been very small. Dr. V. Lepel has made experiments, therefore, with a slowly moving atmosphere, and under different conditions of pressure, and with various types of spark discharge, with the result that he has already increased the amount of combination to 10 per cent. of the total amount of air employed. The air is exposed under increased pressure to a series of parallel spark discharges in the same tube. The change of atmosphere is not made continuously, but intermittently, and the gases are expelled from the discharge tube into a large absorption vessel in which the products are absorbed in a solution of water, or of a caustic alkali. Detailed accounts are given in the memoir of the efficacy of the various forms of high tension discharge, and Dr. V. Lepel is now experimenting with the discharge from a Töpler influence machine with sixty-six rotating plates. Of particular interest are his remarks concerning the probable effect of the high voltage discharges of which we have lately heard so much. He considers it not improbable that by their aid a new mode of producing nitric acid from the atmospheric gases on the large scale may be introduced, rendering us altogether independent of the natural nitrates as a source of nitric acid.

The additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from North Borneo, presented by the Rev. Augustus D. Beaufort; two Small Hill Mynahs (*Gracula religiosa*) from India, presented by Lieut.-Col. W. S. Hore; a Chough (*Pyrrhocorax graculus*) from the Aran Islands, Galway, presented by Miss Balfour; four Sœmmerring's Pheasants (*Phasianus sœmmerringi* ♂ ♂ ♀ ♀) from Japan, presented by Mr. Frank Walkinshaw; an Æsculapian Snake (*Coluber æsculapii*), a Vivacious Snake (*Tachymenis vivax*) from Central Europe, presented by Mr. Alfred Scrivener; a Cayenne Lapwing (*Vanellus cayennensis*) from South America, two Axolotls (*Siredon mexicanus*) from Mexico, purchased; a Ruddy-headed Goose (*Bernicla rubidiceps* ♀) from the Falkland Islands, received in exchange; a Burchell's Zebra (*Equus burchellii* ♂); a Thar (*Capra jemlaica*), a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Variable Nebulæ.—Mr. Barnard, in *Astronomische Nachrichten*, No. 3097, mentions the cases of two nebulæ which he supposes must be of a variable type. The first has a diameter of about 1′, and appears rather like a comet, the brightness gradually increasing towards the centre, there being no nucleus. Its position for 1889·0 was R.A. 3h. 56m. 17s., Declination + 69° 30′ 38″. The other nebula was discovered by him in 1888, and was estimated to lie between magnitudes 9 and 10, the stellar nucleus being of the thirteenth magnitude. Subsequent observations made in 1891 showed that this nebula had become considerably fainter (13½ mag.), there being still a faint nucleus visible; its diameter was estimated as ½′, while its position for 1888·0 was R.A. 0h. 37m. 55·7s., Decl. − 8° 48′ 6″·5.

Variation of Latitude.—Mr. Chandler, toward the latter end of last year, contributed to the *Astronomical Journal* several articles on the variation of terrestrial latitudes, in which the following points were brought out:—(1) This variation is truly terrestrial. (2) The period of revolution, from 1863 to 1885, of the pole of the earth's figure round that of rotation amounted to 427 days in a west to east direction. (3) About the year 1730, the length of this period was a little over a year. (4) The velocity of rotation is slowly diminishing. In the present number (267) of the same journal he brings together evidence to establish some further conclusions at which he has arrived, basing them on a very considerable number of series of observations. The results may be briefly summarized as follows:—(*a*) About 1774 the rate of angular motion of the pole was a maximum with a daily rate of 1°·034, and since that period the decrease has taken place at an accelerating rate. (*b*) If θ be the daily angular motion and T the interval in days from September 18, 1875, the angular velocity of the polar motion may be put in the form

$$\theta = 0^\circ{\cdot}852 - 0^\circ{\cdot}000\,009\,8\,T - 0^\circ{\cdot}000\,000\,000\,132\,T^2,$$

(*c*) The law of the periodic variation may be expressed as follows:—

$$\phi = \phi_0 - 0''{\cdot}22 \cos [\lambda + (t - T)\theta],$$

where T is the time when the north pole of the earth's figure passes the Greenwich meridian,
E the number of completed revolutions between a given date, t, and the adopted epoch,
θ the daily angular motion,
ϕ the instantaneous value of the latitude of a place,
ϕ_0 the mean latitude,
and λ the longitude of the same place,

the values of T and θ being obtained from the equations—

$$T = 1875 \text{ Sept. } 18{\cdot}5 + 422^d{\cdot}56\,E + 1^d{\cdot}034\,E^2 + 0^d{\cdot}009\,E^3 + 0^d\,000067\,E^4,$$

$$\theta = \frac{360^\circ}{P},$$

when $P = 423^d{\cdot}62 + 2^d{\cdot}0953\,E + 0^d{\cdot}0274\,E^2 + 0^d{\cdot}000268\,E^3.$

(*d*) A sensibly constant angular distance between the poles of figure and rotation during the last fifty years has been maintained.

(*e*) By a comparison of absolute and differential determinations the variation is entirely due to zenithal alterations, and not to a simultaneous variation of the zenith and the astronomical pole.

Comparative Spectra of High and Low Sun.—Mr. Edward Stanford has just published five plates, 16¾ × 19⅝ inches, in portfolio form, of Mr. McClean's beautiful comparative photographic spectra of the high and low sun from H to A. The collotype prints have been reproduced from the mounted photographs by the Direct Photo-Engraving Company, and are enlarged about 8½ times from the original negatives. Published simultaneously also are his comparative spectral photographs of the sun and metals, extending from above H to near D. The two series include the platinum and iron-copper groups.

The Coronoidal Discharges.—The discovery of the presence and power of electricity is, comparatively speaking, very modern, and it is only now we are finding out the diversity of results it is capable of producing. The sun being our great source of heat and light, it is only natural that we should suspect him of having a greater quantity of this form of energy in some way or the other, on a scale, of course, very much greater than ours. In a paper read before the National Academy of Sciences, Washington, and published in the June number of the *American Journal of Science*, Mr. M. I. Pupin describes a series of experiments that he has been carrying out with regard to electrical discharges through poor media. The apparatus which he used is fully described, so we will only refer to the plates which illustrate the points he wished to emphasize. The illustrations are from photographs of discharges taken under conditions under which the solar corona is observed, and suggest in a very striking manner the phenomena that are usually observed at these times. In one case, when the vacuum was very poor, the discharge started in the form of four large streamers, together with large jets, their distribution over the whole surface of the sphere being more or less uniform. The appearance of the sphere "reminded me very much of the granular structure of the sun's disk, . . . and the very luminous points which appeared from time to time . . . reminded me . . . of the sun's faculæ." Further experiments regarding the rotational motion of the streamers lead him to conclude that two discharge streamers tended to blow each other out, "owing to the motion of the cooler gas between them, this motion being produced by the enormous heating effect of the discharge." The figures shown are very striking indeed, and represent the general appearances of the corona during eclipses with a remarkable degree of accuracy.

GEOGRAPHICAL NOTES.

M. Joseph Martin, well-known on account of his explorations in North-eastern Siberia, has died at Marghilan while on a journey in Central Asia.

The Kalahari Desert has been crossed successfully by a "trek" of 150 waggons from the Rustenburg district of the Transvaal, bound for Mossamedes, where an active Boer colony has been established, a large party having embarked at Cape Town to join the overland division. Later reports affirm that a Boer republic has been declared in the plateau region of Angola, one of the healthiest parts of tropical Africa.

THE survey of the district surrounding Aden has been completed by the officers of the Survey of India Department after a very arduous campaign. Work was on several occasions almost stopped by sickness, and by the open hostility of the natives.

STIMULATED by the recent discovery of two complete mammoth carcases in the Government of Irkutsk, the St. Petersburg Academy of Sciences has commissioned Prof. Tcherski, of Irkutsk, to proceed to Yakutsk, on the Lena, and thence, accompanied by Cossacks and pack-horses, eastward to the Kolyma Valley, pushing on if possible this summer to Nizhne Kolymsk in 69° N., returning before winter to Sachiversk on the Indigirka, a town situated on the Arctic Circle. The main object of the expedition is to study the drift geology, but collections will be made in all departments of science, including barometric observations, in order to determine the orography of this rarely visited part of Siberia.

Globus announces the formation of a new islet in the Caspian, near Baku, by upheaval. It lies three and a half miles from shore, and measures 175 feet by 100 feet, rising about 20 feet above the water. Its surface is irregular, and composed of blackish-grey and yellow hardened mud.

WITH reference to the note on p. 65 as to the discovery of a new range of mountains in Benin, it is only fair to former travellers in that region to say that the map by the Intelligence Department, although bearing no mountain shading, has marked upon it "Mt. Ara," very near the position where the range seen by Governor Carter is situated.

THE mountaineering expedition, led by Mr. Conway, to attempt the ascent of the loftiest Himalayan summits, has been making excursions from Gilgit and mapping the Bagrot Valley, but bad weather has prevented any very important climbing from being done. A *Times* telegram from Calcutta conveys news of June 8 from Gilgit, from which it appears that the greatest height yet reached is 17,000 feet, one night having been passed at an elevation of 15,600 feet. The party was about to set out for Nagar, *en route* for Askoley, by the Hissar Pass.

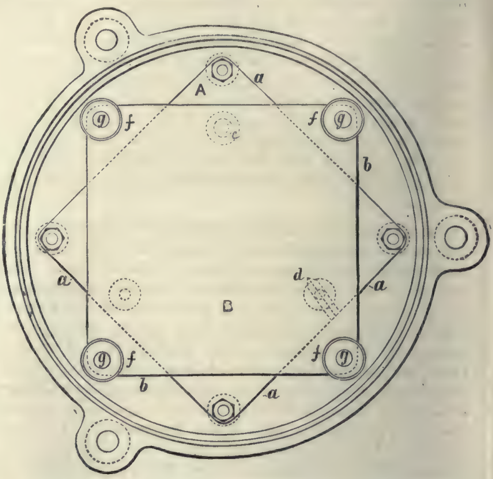
A NEW FORM OF AIR LEYDEN.[1]

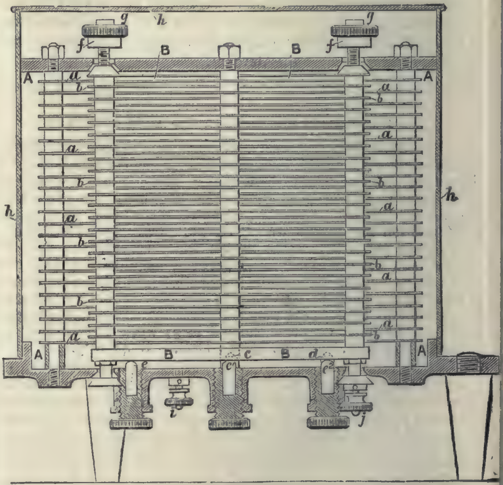
IN the title of this paper as originally offered for communication "*Air Condenser*" stood in place of "*Air Leyden,*" but it was accompanied by a request to the Secretaries to help me to a better designation than "Air Condenser" (with its ambiguous suggestion of an apparatus for condensing air), and I was happily answered by Lord Rayleigh with a proposal to use the word "leyden" to denote a generalized Leyden jar, which I have gladly adopted.

The apparatus to be described affords, in conjunction with a suitable electrometer, a convenient means of quickly measuring small electrostatic capacities, such as those of short lengths of cable.

The instrument is formed by two mutually insulated metallic pieces, which we shall call A and B, constituting the two systems of an air condenser, or, as we shall now call it, an air leyden. The systems are composed of parallel plates, each set bound together by four long metal bolts. The two extreme plates of set A are circles of much thicker metal than the rest, which are all squares of thin sheet brass. The set B are all squares, the bottom of which is of much thicker metal than the others, and the plates of this system are one less in number than the plates of system A. The four bolts binding together the plates of each system pass through well-fitted holes in the corners of the squares; and the distance from plate to plate of the same set is regulated by annular distance pieces which are carefully made to fit the bolt, and are made exactly the same in all respects. Each system is bound firmly together by screwing home nuts on the ends of the bolts, and thus the parallelism and rigidity of the entire set is secured.

The two systems are made up together, so that every plate of B is between two plates of A, and every plate of A, except the two end ones, which only present one face to those of the opposite set, is between two plates of B. When the instrument is set up for use, the system B rests by means of the well-known "hole slot and plane arrangement,"[1] engraved on the under side of its bottom plate, on three glass columns which are attached to three metal screws working through the sole plate of system A. These screws can be raised or lowered at pleasure, and by means of a gauge the plates of system B can be adjusted to exactly midway between and parallel to the plates of system A. The complete leyden stands upon three vulcanite feet attached to the lower side of the sole plate of system A.





In order that the instrument may not be injured in carriage, an arrangement, described as follows, is provided, by which system B can be lifted from off the three glass columns and firmly clamped to the top and bottom plates of system A.

The bolts fixing the corners of the plates of system B are made long enough to pass through wide conical holes cut in the top and bottom plates of system A, and the nuts at the top end of the bolts are also conical in form, while conical nuts are also fixed to their lower ends below the base plate of system A. Thumbscrew nuts, *f*, are placed upon the upper ends of the bolts after they pass through the holes in the top plate of system A.

---

[1] "On a New Form of Air Leyden, with Application to the Measurement of Small Electrostatic Capacities." By Lord Kelvin, P.R.S. Read at the Royal Society on June 2.

[1] Thomson and Tait's "Natural Philosophy," § 198 example 3.

When the instrument is set up ready for use, these thumbscrews are turned up against fixed stops, *g*, so as to be well clear of the top plate of system A; but when the instrument is packed for carriage they are screwed down against the plate until the conical nuts mentioned above are drawn up into the conical holes in the top and bottom plates of system A; system B is thus raised off the glass pillars, and the two systems are securely locked together so as to prevent damage to the instrument.

A dust-tight cylindrical metal case, *h*, which can be easily taken off for inspection, covers the two systems, and fits on to a flange on system A. The whole instrument rests on three vulcanite legs attached to the brass plate on system A; and two terminals are provided, one, *i*, on the base of system A, and the other, *j*, on the end of one of the corner bolts of system B.

The air leyden which has been thus described is used as a standard of electrostatic capacity. In the instrument actually exhibited to the Society there are twenty-two plates of the system B, twenty-three of the system A, and therefore forty-four octagonal air spaces between the two sets of plates. The thickness of each of these air spaces is approximately 0·301 of a centimetre. The side of each square is 10·13 cm., and therefore the area of each octagonal air space is 85·1 sq. cm. The capacity of the whole leyden is therefore approximately $44 \times 85\cdot1/(4\pi \times \cdot287)$, or 1038 cm. in electrostatic measure. This is only an approximate estimate, founded on a not minutely accurate measurement of dimensions, and not corrected for the addition of capacity, due to the edges and projecting angles of the squares and the metal cover. I hope to have the capacity determined with great accuracy by comparison with Mr. Glazebrook's standards in Cambridge.

To explain its use in connection with an idiostatic electrometer for the direct measurement of the capacity of any insulated conductor, I shall suppose, for example, this insulated conductor to be the insulated wire of a short length of submarine cable core, or of telephone, or telegraph, or electric light cable, sunk under water, except a projecting portion to allow external connection to be made with the insulated wire.

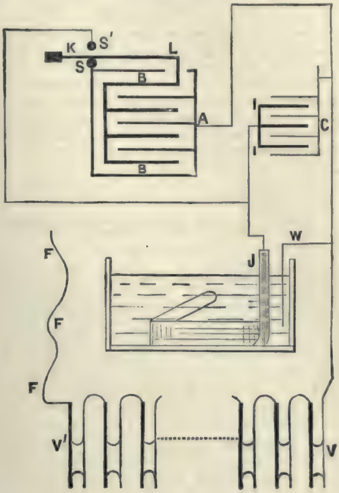
The electrometer which I find most convenient is my "multicellular voltmeter," rendered practically dead-beat by a vane under oil hung on the lower end of the long stem carrying the electric "needles" (or movable plates). In the multicellular voltmeter used in the experimental illustration before the Royal Society, the index shows its readings on a vertical cylindric surface, which for electric light stations is more convenient than the horizontal scale of the multicellular voltmeters hitherto in use; but for the measurement of electrostatic capacity the older horizontal scale instrument is as convenient as the new form.

To give a convenient primary electrification for the measurement, a voltaic battery, *vv*′, of about 150 or 200 elements, of each of which the liquid is a drop of water held up by the capillary attraction between a zinc and copper plate about 1 mm. asunder. An ordinary electric machine, or even a stick of rubbed sealing-wax, may, however, be used, but not with the same facility for giving the amount of electrification desired as the voltaic battery.

One end of the voltaic battery is kept joined metallically to a wire, W, dipping in the water in which the cable is submerged, and with the case C of the multicellular, and with the case and plates A of the Leyden, and with a fixed stud, S, forming part of the operating key to be described later. The other end of the voltaic battery is connected to a flexible insulated wire, FFF, used for giving the primary electrification to the insulated wire J of the cable, and the insulated cells, II, of the multicellular kept metallically connected with it. The insulated plates B of the leyden are connected to a spring, KL, of the operating key referred to above, which, when left to itself, presses down on the metal stud S, and which is very perfectly insulated when lifted from contact with S by a finger applied to the insulating handle H. A second well insulated stud, S′, is kept in metallic connection with J and I (the insulated wire of the cable and the insulated cells of the multicellular).

To make a measurement, the flexible wire F is brought by hand to touch momentarily on a wire connected with the stud S′, and immediately after that a reading of the electrometer is taken and watched for a minute or two to test either that there is no sensible loss by imperfect insulation of the cable and the insulated cells of the multicellular, or that the loss is not sufficiently rapid to vitiate the measurement. When the operator is satisfied with this, he records his reading of the electrometer, presses up the handle H of the key, and so disconnects the plates B of the leyden from S and A, and connects them with S′, J, I. Fifteen or twenty seconds of time suffices to take the thus diminished reading of the multicellular, and the measurement is complete.

The capacity of the cable is then found by the analogy:—As the second reading of the electrometer is to the excess of the first above the second, so is the capacity of the leyden to the capacity of the cable.



A small correction is readily made with sufficient accuracy for the varying capacity of the electrometer, according to the different positions of the movable plates, corresponding to the different readings, by aid of a table of corrections determined by special measurements for capacity for the purpose on the multicellular.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Prof. Liveing announces a course of lectures in general chemistry, to be given during the Long Vacation by Mr. Fenton, beginning on July 7. Mr. Fenton will also give a series of demonstrations on the chemistry of photography.

At the Congregation on June 16, seven graduates in arts were admitted to the degree of Doctor in Medicine, and thirty-one to the degrees of Bachelor of Medicine and Bachelor of Surgery. These are the largest numbers hitherto admitted at one time.

Sir R. S. Ball, Lowndean Professor of Geometry and Astronomy, has been elected to a Professorial Fellowship at King's College.

At Christ's College the following awards have been made to students of natural science:—Scholarships: E. K. Jones (£50), G. A. Anden (£30), J. M. Woolley (£30), C. F. G. Masterman (£50), H. Pentecost (£50), A. M. Hale (£30). Exhibition: A. M. Barraclough (£30). At Emmanuel College:—Scholarship: A. Eichholz (£80). Exhibition: J. C. Muir (£30).

At the annual election of scholars in St. John's College, the following awards in Natural Science have been made:—Foundation Scholarships: W. L. Brown, T. L. Jackson, W. McDougall, S. S. F. Blackman. Exhibitions in Augmentation of Scholarships: Villy, Whipple (First Class Nat. Sci. Tripos, Part II.). Hughes Prize (highest in third year): Villy. Herschel Prize in Astronomy: Pocklington. Hutchinson Studentship for Research in Zoology: E. W. MacBride.

SCIENTIFIC SERIALS.

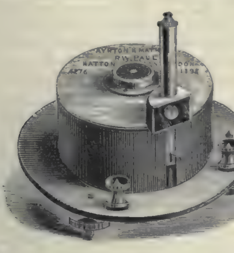
THE numbers of the *Journal of Botany* for May and June appeal almost entirely to students of systematic and descriptive botany:—Mr. F. J. Hanbury continues his notes on *Hieracia* new to Britain, in the course of which he describes three species altogether new.—Mr. Geo. Massee contributes diagnoses of a number of new species of Fungi from St. Vincent, illustrated by three coloured plates.—Mr. E. G. Baker continues his Synopsis of genera and species of *Malveæ;* Rev. Moyle Rogers his essay at a key to British *Rubi;* and Mr. W. A. Clarke his first records of British flowering plants.

IN the *Botanical Gazette* for May are two original papers of interest:—On the archegone and apical growth of the stem in *Tsuga canadensis* and *Pinus sylvestris*, by D. M. Mottier. On the first point the author agrees very nearly with the account by Strasburger; on the second point he is unable to say that there is a single cell at the apex of the stem, unless in the young plant, and even then not with absolute certainty.—Germination of the teleutospores of *Ravenalia cassiæcola*, by B. M. Duggar.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, June 10.—Mr. Walter Baily, Vice-President, in the chair.—Dr. Gladstone read a paper on some points connected with the electromotive force of secondary batteries, by himself and Mr. W. Hibbert. The communication includes replies to certain questions raised by M. Darrieus in a paper read before the Société Internationale des Électriciens on May 4, 1892; and to the views expressed by Prof. Armstrong and Mr. Robertson in the discussion on a paper by the present authors read before the Institution of Electrical Engineers, on May 12 and 19. It also contains an account of their recent experiments on the subject. M. Darrieus agrees with Prof. Armstrong and Mr. Robertson that the large E.M.F. immediately after charge is due to persulphuric acid, and opposes the ordinary theory that the ultimate product of discharge is lead sulphate at both plates, so far as the positive plate is concerned. The authors attribute the finding of large quantities of lead oxide by M. Darrieus to difficulties in analysis, for it is not easy to imagine that oxide of lead could remain as such in presence of sulphuric acid. They have also shown that the changes of E.M.F. during charge and discharge coincide fairly well with those obtained by putting Pb and PbO_2 plates in different strengths of acid, and conclude "that the changes of E.M.F. . . . depend on the strength of the acid that is against the working surfaces of the plates." Prof. Armstrong and Mr. Robertson disagree with the authors' views, and suppose that the sulphuric acid used was contaminated with soluble peroxides; and they also believe that H_2SO_4 itself takes part in the reactions. As regards the first objection, the authors see no reason why the traces of soluble peroxide (if any) on the plates should always vary in amount with the strength of the fresh acid in which the plates were dipped. The second point they leave an open question. In reply to the criticism on the summation of the two curves obtained respectively with two lead plates and two lead peroxide plates in acids of different strengths, they point out that the resulting curve coincides both in shape and magnitude with that determined when a Pb and a PbO_2 plate were placed in different strengths of acid. Whilst admitting the possibility of the lead supports having some influence on the result, they cannot conceive that such large and uniform differences as those given in their paper can be due to accidental operations of local action. To show that the increase of E.M.F. does not depend on the presence or absence of persulphuric acid, the authors have tested the E.M.F. of a Pb and a PbO_2 plate, free from soluble oxides, in sulphuric acid of 15 per cent. strength, a porous diaphragm being between the plates. The E.M.F. was 1·945 volts. After adding 1 per cent. of persulphate of potassium to the liquid surrounding the PbO_2 plate, the E.M.F. was unaltered; whilst putting the Pb plate in the same liquid only reduced the E.M.F. to 1·934. Experiments had also been made on cells with phosphoric acid of different strengths, instead of sulphuric acid. Changing the density from 1·05 to 1·5, raised the E.M.F. 0·176 volt, whilst calculations from Lord Kelvin's law gave 0·171 volt. In this case they consider that no acid analogous to persulphuric acid could be present. They also find that the effects of charging and repose on the E.M.F. of phosphoric acid cells are quite analogous to those obtained with sulphuric acid. The researches are being extended chiefly on the thermochemical side. Prof. Ayrton thought there was no question that the strength of acid had much to do with the changes of E.M.F. The point at issue, he considered, was whether the changes were direct effects of the strength of acid, or due to secondary actions brought about by alterations in strength. Mr. E. W. Smith said Mr. Robertson and himself were repeating the author's experiments with two PbO_2 plates without any grid. They had obtained results analogous to those mentioned in the paper, but the true explanation of the effects was still to seek. Mr. W. Hibbert contended that the soluble oxides referred to by Prof. Armstrong and Mr. Robertson were not present in their experiments. They had also proved that changes in acid strength altered the E.M.F., whilst presence of persulphuric acid did not. Dr. Gladstone, in reply, said they also were making experiments without grids, but had not made sufficient progress to discuss them at present. Mr. Hibbert and himself believed the effects of local action inconsiderable, whilst Messrs. Armstrong and Robertson thought them very important. He hoped that ere long the points would be settled conclusively.—A paper on workshop ballistic and other shielded galvanometers, by Prof. W. E. Ayrton, F.R.S., and Mr. T. Mather, was read by Prof. Ayrton. The galvanometers described were of the type having movable coils and fixed magnets, the advantages of which are well known. In designing the ballistic instruments, their aim had been to obtain sensibility and portability, combined with being screened from external influences, for it was often desirable to measure the magnetic fluxes and fields in dynamos by apparatus near the machines. One of the improvements adopted was the narrow coil described in a paper "On the Shape of Movable Coils, &c.," read before the Society in 1890. Such coils are particularly advantageous for ballistic instruments, for not only can greater swings be obtained by the discharge of a given quantity of electricity through such a coil than with ordinary shaped coils when the periodic times are the same, but even when the same control is used, the same length of wire in the coil, and suspended in the same field, the narrow coil is more sensitive to discharges than coils of any other shape. Another improvement was the use of phosphor bronze strip for the suspensions instead of round wire. For a given tensile strength, both the control and the subpermanent set could be diminished by using strip. In February 1888 the authors made a d'Arsonval of the ordinary type as a ballistic instrument, and found that although it was suitable for comparing condensers, yet for induction measurements the damping was excessive unless the resistance in the circuit was very large. This greatly reduced the sensitiveness. In 1890 they tried one of Carpentier's milliamperemeters as a ballistic instrument, but found it insensitive. A narrow coil instrument made in the same year was found to be sensitive for currents; but as the coil was wound on copper to get damping, it was not suitable for ballistic work. In January 1892 a somewhat similar instrument was constructed for ballistic purposes, and was found very sensitive and convenient. Although the coil had only a resistance of 13 ohms, one microcoulomb gave a swing of 170 divisions on a scale 2000 divisions distant, the periodic time being 2·7 seconds. The instrument could be used near electromagnets or dynamos, and was so sensitive that for ordinary induction measurements very large resistances can be put in series with it, thus reducing the damping to a very small amount. On the other hand, the coil could be brought to rest immediately by a short circuit key. It had the further advantage that it was not necessary to redetermine its constant every time it was used. The chief disadvantage of such instruments was the variable damping on closed circuits of different resistances. This could, however, be overcome by arranging shunts and resistances so that the external resistance between the galvanometer terminals was the same for all sensibilities. A portable ballistic instrument, intended for workshop use, was next described. This had a narrow coil and a pointer moving over a dial whose whole circumference was divided into 200 parts. The instrument had been designed to give a complete revolution for a reversal of a flux of two million C.G.S. lines, but the pointer could turn through two or more revolutions. To test strong fields a test coil with a total area of 10,000 square centimetres is used, and has a trigger arrangement for suddenly twisting it through two right angles. The instrument then reads off directly the strength of field in C.G.S. lines. To vary the sensitiveness in known proportions, resistances are employed. Referring to the improvements made in movable coil instruments since January 1890, when a paper on "Galvanometers" was read before the Society by Dr. Sumpner and the present authors, Prof. Ayrton said Mr. Crompton had greatly increased the sensitiveness of Carpentier's instruments by suspending the coils with phosphor-bronze strip. Mr. Paul had brought out a narrow-coil instrument which combined the advantages of portability, dead-beatness, quickness, and sensibility. Specimens of these instruments were exhibited. The narrow coils are inclosed in silver tubes, which serve to damp the oscillations. Such a coil is suspended within a brass tube which also forms the mirror chamber, and slides down between the poles of a circular magnet fixed to the base. To clamp the coil, a plug mounted on a slotted spring passes through a hole in the brass tube. A tube can be taken out and replaced by another containing a coil of different resistance in a few seconds. An instrument of this kind, with a coil of 300 ohms, gave 95 divisions per microampere, and the damping on open circuit was such that any swing was $\frac{1}{15}$ of the previous one. On comparing recent instruments with those mentioned in the paper on galvanometers above referred to, a distinct improvement is apparent, for their sensitiveness is, for the same resistance and periodic time, as great as that of Thomson instruments. Prof. Perry remarked that the forces dealt with were extremely small. Mr. Swinburne thought that ballistic galvanometers might be regarded as instruments indicating the time integral of E.M.F. rather than quantity. Illustrating his meaning by reference to dynamos, he said that if two machines arranged as dynamo and motor were joined by wires, then, if the armature of the dynamo were turned through any angle, that of the motor would move through the same angle, supposing friction, &c., eliminated. Speaking of figures of merit, he pointed out that the power consumed was the important factor. Prof. S. P. Thompson inquired what was the longest period yet obtained with narrow-coil instruments. The decay of magnetism in large dynamos was so slow that very long periods were required. He himself had used a weighted coil for such measurements. He also wished to know why the figures of merit were expressed in terms of scale divisions on a scale at 2000 divisions distance, instead of in angular measure or in tangents. Mr. E. W. Smith asked what was the length of strip required to prevent permanent set when the deflection exceeded a revolution. Mr. A. P. Trotter thought that, in testing magnetic fluxes by the workshop ballistic instrument, the test coil might be left in circuit instead of putting in another coil. He wished to know what error was introduced by the change of damping caused by the resistance of the circuit not being quite constant. In his reply, Prof. Ayrton said Mr. Boys had pointed out that the scientific way to lengthen period was not by weighting the coils or needles, but to weaken the control. Periods of 5 seconds had been obtained. At present it was not easy to obtain longer periods owing to difficulties in obtaining sufficiently thin strip, and to the magnetism of materials.



Zoological Society, June 14.—Prof. W. H. Flower, C.B., F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of May 1892, calling special attention to a pair of the rare and beautiful Passerine bird the Grey Coly-Shrike (*Hypocolius ampelinus*) from Fao, Persian Gulf, presented by Mr. W. D. Cumming. He also made some remarks on the most interesting objects observed during a recent visit to the Zoological Gardens of Rotterdam, the Hague, Amsterdam, and Antwerp.—A communication from Mr. T. D. A. Cockerell contained particulars of the occurrence of a species of Jacana (*Jacana spinosa*) in Jamaica.—Dr. John Anderson, F.R.S., exhibited and made remarks on some specimens of the Mole-Rat (*Spalax typhlus*) from Egypt.—Prof. Romanes gave an account of some results recently obtained from the cross-breeding of Rats and of Rabbits, and showed that it did not follow that a blending of the characters of the parents was the result of crossing two different varieties.—Prof. Howes exhibited and made remarks on some photographs received from Prof. Parker, of Otago, New Zealand, illustrative of Sea-Lions, Penguins, and Albatrosses in their native haunts.—Dr. Dawson made remarks on the Fur-Seal of Alaska, and exhibited a series of photographs illustrating the attitudes and mode of life of these animals.—Mr. Sclater called attention to the habits of a South African Snake (*Dasypeltis scabra*) as exhibited by an example now in the Society's Gardens.—Mr. Sclater also read some extracts from a letter addressed to him by Mr. H. H. Johnston, C.B., announcing the despatch of a consignment of natural history specimens illustrative of the fauna and flora of the Shiré Highlands.—Mr. W. Saville Kent exhibited and made remarks on some photographs of a species of the genus *Podargus*, showing the strange attitudes of these birds in a living state.—Mr. F. E. Beddard read a paper on the brain and muscular anatomy of *Aulacodus*.—Mr. Gerard W. Butler read a paper on the subdivision of the body-cavity in Snakes, being a continuation of the subject treated of in a memoir on the subdivision of the body-cavity in Lizards, Crocodiles, and Birds, previously read before the Society.—Mr. J. W. Gregory gave an account of his researches on the British Palæogene Bryozoa, of which he recognized thirty species, represented in the National Collection by about 750 specimens.—Mr. Sclater gave an account of a small collection of Birds from Anguilla, West Indies, made by Mr. W. R. Elliott, one of the collectors employed by the Committee for the exploration of the Lesser Antilles.—Prof. G. J. Romanes, F.R.S., read a paper on a seemingly new diagnostic character of the Primates, which was that the terminal joints of both hands and feet in all species of this Order are destitute of hairs. This rule did not apply to the Lemurs.—Mr. O. Thomas read a paper on the genus *Echinops*, of the order Insectivora, and gave notes on the dentition of the allied genera *Ericulus* and *Centetes*.—Mr. G. A. Boulenger gave an account of the Reptiles and Batrachians collected by Mr. C. Hose on Mount Dulit, North Borneo. Amongst these was a fine new Lizard of the genus *Varanus*, proposed to be called *V. heteropholis*. Two new Batrachians were also described as *Rhacophorus dulitensis* and *Nectophryne hosii*.—A paper was read by Lieut.-Colonel H. H. Godwin-Austen, F.R.S., on new species and varieties of the Land-Molluscan genus *Diplommatina*, collected by himself, and more recently by Mr. W. Doherty, in the Naga and Munipur Hill ranges. The author described twenty-seven supposed new species, the most remarkable being *D. unicrenata*, with a peculiarly formed peristome.—A communication was read from Mr. B. B. Woodward on the mode of growth and the structure of the shell in *Velates conoideus*, Lamk., and in other *Neritidæ*. The mode of growth and the structure of this shell were described as follows: Up to a certain point the growth is normal; a change in the direction of growth afterwards takes place, and the test is enlarged by the addition of fresh shelly matter on the exterior of the under side, and by the removal of previously-formed layers on the inner surface. The internal septum that serves the purpose of a myophore was shown to have originated in the paries, which, in the course of growth, had been replaced by the septum. In this respect *Velates conoideus* epitomized in its life-history conditions which are found in distinct recent species of the closely-allied genus *Neritina*. The relations of the paries and septum in this last genus were also described in this paper.—This meeting closes the present session. The next session (1892–93) will commence in November 1892.

PARIS.

Academy of Sciences, June 20.—M. d'Abbadie in the chair.—Phenomena of the residual life of muscle taken from the living being: physiological action of the muscular bases, by MM. Arm. Gautier and L. Landi.—On the influence of mineral filters on liquids containing substances produced by microbes, by M. Arloing.—On the sanitary system adopted by the Venice Conference to prevent cholera from penetrating into Europe through the Isthmus of Suez, by M. P. Brouardel. Four previous conferences for the reform of the quarantine system having failed, that convened at Venice in January 1892 has at last adopted a system chiefly advocated by the French delegates, and practically tested on the Pyrenees frontier during the cholera in Spain two years ago. On that occasion the passengers' linen was disinfected in heating ovens by steam under pressure, and the cholera patients, real or suspected, were isolated. It having been shown that it is practically impossible for a vessel to pass the Suez Canal in quarantine, without contact with the shores, it was resolved that no vessel should be allowed to pass into the Mediterranean unless it was free from infection or had been completely disinfected. Vessels from the Orient which have had no case of cholera since their departure will be allowed a perfectly free passage. Those which have had cases of cholera during the voyage, but none for seven days before arrival, will be allowed to pass the Canal in quarantine if they have a medical officer and a disinfecting stove on board. If not, they will be retained at the entrance of the Canal, where a sanitary station will be erected, and where the disinfection will take place. Infected vessels will be detained at the entrance, the patients will be disembarked and isolated, and the vessels will be disinfected. It is calculated that, out of 16,000 vessels that have passed through the Canal in five years, under the regulations now adopted 28 would have had to undergo a delay of a few hours for disinfection, and 2 would have been detained for a few days.—On the law of correspondence of tangent planes in the transformation of surfaces by curved symmetry, by M. S. Mangeot.—On the distribution of pressures in a rectangular solid charged transversally, by M. Flamant.—On the law of resistance of the cylinders utilized in the crusher manometers, by M. P. Vieille.—On the Doppler-Fizeau method, by M. Moessard. If the relative motions of the source and the observer be alone considered, without reference to the distortion of the wave-front due to motion through the connecting medium, the ratio of the real to the apparent wave-length will be $\frac{V}{V - v + v'}$, where V is the velocity of wave propagation, v that of the source, v' that of the observer. The true formula for this ratio is $\frac{V - v'}{V - v'}$, which, in the case of $V = v$, will differ from the former by infinity.—An examination of the possibility of a reciprocal action between an electrified body and a magnet, by M. Vaschy. Showing that such an action cannot exist unless it be due to a physical quality of the ether different from that implied by the coefficients k and k' in the electric and magnetic laws of attraction, viz. $f = k\frac{qq'}{r^2}$, and $f = k'\frac{mm'}{r^2}$.—Action of nitric oxide on the metallic oxides, by MM. Paul Sabatier and J. B. Senderens. —On a bromo-nitride of phosphorus, by M. A. Besson.—On permolybdic acid, by M. E. Péchard.—On the alteration of preserved ferruginous mineral waters, by M. J. Riban.—On the transformation of gallic acid into pyrogallol: fusion point of pyrogallol, by M. P. Cazeneuve.—On the intestinal calculi of the cachalot (*ambre gris*), by M. Georges Pouchet.—The heliotropism of the *Nauplius*, by M. C. Viguier.—Researches on the proximate composition of vegetable tissues, by M. G. Bertrand. —On the action of some mineral salts on lactic fermentation, by M. Ch. Richet.—On the respiratory exchange, by MM. Chr. Bohr and V. Henriquez. An account of experiments showing that the lungs are not only the seat of the process of gaseous exchange, but also of the oxidation of tissue elements.—Origins and trophic centres of the vaso-dilatatory nerves, by M. J. P. Morat.—Researches on the requirements of the vine, by M. A. Muntz.—On the topography of some lakes of the Jura, the Bugey, and the Isère, by M. A. Delebecque.

AMSTERDAM.

Royal Academy of Sciences, May 28.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Behrens dealt with specimens of brass made by compression of the constituents at ordinary temperature by Prof. W. Spring, Liége, Belgium. One of the specimens, kindly forwarded by Prof. Spring, was of a reddish colour, and had been produced by compressing a mixture of 9 parts of copper and 1 part of zinc; another, pale yellow, by compressing a mixture of 7 parts Cu and 3 parts Zn. Both specimens had been filed up twice, and again consolidated by pressure. The reddish metal was a little softer than common cast brass; it could be somewhat flattened under the hammer. The yellow metal was harder than common brass, and brittle. Both varieties contain a great quantity of yellow alloy, which seems to be in an amorphous state, showing a uniform, finely granular appearance, without any vestige of the beautiful crystallites, so characteristic for copper-zinc alloys, obtained by fusion. Further, a good deal of angular fragments of red copper, some of them cracked and doubled up, with yellow threads between the red lumps and strands, and finally some zinc, angular fragments and threads, trending outwards and uniting near the curved surface of the cylindrical specimens. The metal is nearly, but not wholly compact. There is much that gives evidence of a flow in the yellow alloy and in the zinc, but nothing pointing to a truly liquid state of the alloy or one of its components. Regelation seems to be put aside, while there does not remain any doubt that zinc and copper have been intimately mixed and actually united by repeated filing and compression. One may venture to say, that a more complete union of metallic powders by compression will lead to alloys of most remarkable properties, and may give some alloys that cannot be produced by fusion.

THURSDAY, JULY 7, 1892.

A SYSTEM OF MINERALOGY.

The System of Mineralogy of James Dwight Dana, 1837–68: *Descriptive Mineralogy*. Sixth Edition. By Edward Salisbury Dana, Professor of Physics, and Curator of the Mineral Collection, Yale University. Entirely rewritten and much enlarged. Pp. lxiii. and 1134. Illustrated with over 1400 Figures. (New York and London: Kegan Paul, Trench, Trübner, and Co., 1892.)

IN the whole history of scientific literature it would be difficult to find a parallel to Dana's "System of Mineralogy," for there is probably no work which, like it, has maintained for more than half a century its position as the best and most complete work of reference on a branch of natural history. In spite of the enormous additions to our knowledge of the chemical and physical properties of well-known minerals, and of the discovery of innumerable new species and varieties, during that long period, the work has been carefully kept up to date; and so thorough and judicious have been the revisions to which successive editions have been subjected, that the book may at the present time fearlessly challenge comparison with the latest and most successful attempts to supply a comprehensive survey of mineralogical science.

When the work first appeared, in 1837, its author made a determined attempt to grapple with the difficult problem of mineralogical nomenclature and classification; like many of his contemporaries, he was sanguine of being able to make the taxonomy of mineralogy correspond with that of the other natural-history sciences, and a so-called *natural* system of classification, based on that of Mohs, was adopted by him. But on the appearance of the third edition in 1850 the futility of all such attempts was admitted, and a scheme of classification founded upon chemical composition was substituted; it is this system of classification which, with some modifications rendered necessary by the progress of discovery, is employed in the present edition.

On reaching its fourth edition in 1854, the work had grown to such an extent that it became necessary to divide it into two volumes: the first devoted to a general introduction to crystallography, with mineral physics and chemistry, and the second to descriptive mineralogy. The necessity for the re-issue of the first of these volumes has been obviated, however, by the publication in 1875 of the "Determinative Mineralogy" by the author's friend and fellow-worker, Prof. Brush, and by the appearance, two years later, of the "Text-book of Mineralogy," in the preparation of which the author had the able cooperation of his son, Prof. Edward Salisbury Dana. In this way the "System of Mineralogy" has now been limited to the descriptive portion of the original work, and only a few pages of introductory matter are given to explain the terminology, symbols, and abbreviations which it has been found necessary to employ. A noteworthy change in the fifth edition, and one which has tended to greatly increase the value of the work for reference purposes, was the fuller recognition and description of varieties, and of the localities from which they have been obtained; the very thorough revision of the historical synonymy, which was undertaken for this fifth edition, also greatly enhanced the usefulness of the book. These historical details and references, which have entailed a vast amount of bibliographical research, have been retained with but few modifications in the present edition.

In the preface to this fifth edition, Prof. Dana wrote in 1868 as follows:—

> "In these and other ways the volume has unavoidably become enlarged. Not a page, and scarcely a paragraph, of the preceding edition remains unaltered, and fully five-sixths of the volume have been printed from manuscript copy. I may here add that, notwithstanding the impaired state of my health, this manuscript—the paragraphs on the pyrognostic characters excepted—was almost solely in the handwriting of the author, or in that of a copyist from it. Neither the consultation of authorities, the drawing of conclusions, nor the putting of the results on paper, has been delegated to another. And being now but half-way between the fifties and sixties, it is my hope that the future will afford another opportunity for similar work."

In writing these lines, Prof. Dana could scarcely have foreseen that the issue of the sixth edition of the work would be delayed for 24 years. During that period three appendices have been prepared by the author, and he has shown, in numerous books and original memoirs on various branches of geology and natural history, an unabated interest and zeal in scientific work. But the very heavy task of incorporating the matter of the appendices into a new edition, and of revising and re-arranging the whole work, has had to be delegated by the author to his son, and certainly it could not have been placed in more competent hands. Every mineralogist will rejoice that the familiar and excellent features of the original work have been carefully preserved. The book, indeed, is so well known to all working geologists and mineralogists, that we cannot do better than to indicate the chief changes which have been found necessary in the present edition, in order to bring it up to date and maintain its high character.

The work now contains more than one-half more matter than the fifth edition, and, to keep it down even to this limit, a very rigid system of abbreviation and condensation has had to be adopted, while the size of the page has been increased by one-fifth. The historical account of the species remains substantially the same as in the last edition, but names commonly employed in important languages, in addition to English, French, and German, have been given.

In the chemical portion of the work very considerable changes have been introduced. The difficult question of the classification of the silicates has received the fullest consideration, and the views of Rammelsberg, Tschermak, and other chemists on each species are clearly indicated. It has no longer been found possible, however, to give a statement of all the analyses that have been made of a species. The microscopic work of Lacroix and others has shown that many of these analyses are worthless, as the material operated upon has been a mixture and not a homogeneous substance. In the present edition all trustworthy analyses of rare minerals have been given, and in the case of common minerals, where the number of published analyses is very great, a judicious selection of the best and most recent analyses has been made.

The statement of the optical constants and the physical characters of minerals has been treated in much the same fashion as the chemical data. The best and most trustworthy determinations have been selected, while measurements of doubtful value have been omitted.

It is on the crystallographic portion of the work, however, that Prof. E. S. Dana has expended the greatest amount of labour. We are informed in the preface that "an attempt has been made to trace back to the original observer the fundamental angles for each species, then the axes have been recalculated from them, and finally the important angles of all common forms have been calculated from these axes." The author is able to state that in every case this recalculation of the angles of all the forms of a mineral has been undertaken, and that no pains has been spared in the verification and correction of the results. The crystal forms are indicated by letters, and the symbols employed are in the first instance those of Miller, and in the second instance the modified form of Naumann's symbols familiar to all who have used the earlier editions of the work. The author gives it as his opinion that the former should eventually supplant the latter altogether. In the hexagonal and rhombohedral system, however, the Bravais-Miller system is adopted in preference to that of Miller.

With few exceptions, the figures of crystals (1400 in number) are new. Many have been drawn from original data, and those taken from other works have been redrawn so as to secure uniformity of projection; the habits of each species and the types of twinning in crystals have been very fully illustrated.

While the general account of the mode of occurrence and association of mineral species has been very carefully attended to, there has been no attempt to make this part of the work exhaustive, for to have done so would have greatly increased the bulk of the volume. The account of American localities—which has always been an important feature of Dana's work, and has made it for North America what the treatises of Kokscharov and Zepharovitch are for the Russian and Austrian Empires respectively—has been greatly added to. The works of Roth and Hintze, with the numerous books and memoirs devoted to the geology of particular regions, now supply all the information that is needed in respect to mineralogical distribution in other areas.

We have tested the volume in many ways as to the completeness and recent nature of the information given with respect to particular species, and always with satisfactory results. To pass such a voluminous mass of information through the press has required eighteen months of labour, and notices of important contributions to our knowledge that have appeared since the earlier pages of the book were printed off have been relegated to a supplement. This supplement, which extends to 28 pages, also contains brief accounts of minerals of unknown composition, and of doubtful species having little or no claim to recognition.

In conclusion, we must congratulate both the original author of the "System," and the writer of the volume in its present form, on the completion of their useful labours. It is not too much to say that the publication of each successive edition of this work has constituted an epoch in the history of mineralogical science; and the present edition, coming from the hands of a new author, completely maintains the prestige of former ones.

J. W. J.

MODERN INFINITESIMAL CALCULUS.

An Introduction to the Study of the Elements of the Differential and Integral Calculus. From the German of the late Axel Harnack, Professor of Mathematics at the Polytechnicum, Dresden. (London and Edinburgh: Williams and Norgate, 1891.)

MR. G. L. CATHCART'S translation forms a handsome volume, and will prove acceptable to those engaged in mathematical teaching, as a storehouse of suggestive methods and ideas for analytical exegesis.

But let us examine the work from the standpoint of the student approaching the subject of the Calculus for the first time, supposing this book to be put into his hands to acquire his first acquaintance with the method and reasoning.

Until very recently the Classics, Greek and Latin, as taught at school, were looked upon chiefly as collections of grammatical examples, and the subject-matter was lost sight of in the careful parsing and analysis of the sentences. Boys were taught on a system which implied that they were all, in their turn, to become schoolmasters and instructors; and the interests of the majority, who would profit intellectually from the literary study of the ancient masterpieces, were completely neglected.

So, too, in Mathematics: the ordinary text-books give an excellent schoolmaster's training in the subject; but the large and increasing class of students, brought into existence recently by the commercial developments of scientific application, who are required to put into immediate practice the theory which they find indispensable, cannot afford the time to be dragged the whole length of the quagmire of the Convergency of Series, of Inequalities, of Discontinuity, and of the so-called Failure of Taylor's Theorem. These are the quagmires in which the mere mathematician delights to lose himself, and also to lure in others after him.

To one who is already very familiar with the notation and operations of the Calculus the present treatise will prove, not repellent, but even fascinating to minds who pursue the subject for its purely analytical interest. Having been over the road before, they will be prepared to appreciate the strictly logical order in which the theorems are developed, starting in Chapter I. with the fundamental conceptions of Rational Numbers, of their Addition, Subtraction, Multiplication, and Division—the subject of Arithmetic in short; and passing on in Chapter II. to Radicals and Irrational Numbers in general. The next three chapters treat of the Conceptions of Variable Quantities, of Functions of a Variable, their Geometric Representation and Continuity; and it is not till the sixth chapter that the Differential Coefficient is introduced and determined for the simplest functions.

But the beginner, who has had the courage to read thus far, will wonder what on earth the subject is all about, even when he has reached the end of Book I., which covers the ground of the subject usually called the Differential Calculus: there are no illustrations, except for one or two meagre geometrical applications, for the mind to hold on by; no diagrams, and no examples to test the soundness of the student's knowledge.

It is true that these collections of examples are decried in certain lofty quarters of the mathematical hierarchy; but the humbler priests of the science, who are in touch with the noviciate mind of human nature, know their practical value; and these collections of problems, formerly a feature of our text-books unknown abroad, are now being extensively copied and adopted in other countries. "In scientiis ediscendis prosunt exempla magis quam præcepta" (Newton).

The Second Book considers Functions of Complex Numbers: we make another fresh start with the operations of Arithmetic, as it is called here; not that any resemblance can be traced to what generally goes by that name. In this book the questions of Convergency, of Single- and Multiple-valued Functions, as illustrated by a Riemann surface, and of their Zeros and Infinities, are gone into at great length; but at the same time the reader will have an impression that the information is given in a very condensed form, and that an attempt has been made to give a brief *résumé* of a subject which requires a large volume to itself.

This Morbid Pathology of the Mathematical Function, as we may call it, requires a very clear, concise, and cosmopolitan tereminology, which, as Mr. Cathcart points out on p. 148, it does not yet possess; it is unfortunate that the nomenclature has mostly been formed originally in the agglutinate German language, and in many cases is only very imperfectly translatable.

This part of the subject, although principally known to us from the researches of later writers, such as Cauchy, Riemann, Dirichlet, and Weierstrass, owes very much to Gauss; but Gauss deserves to lose the credit of priority, from his baneful habit of bottling up his discoveries, after announcing that he had obtained the solution, so as to warn off all other investigators from his preserves of research.

The Integral Calculus is developed in Book III.; here also the treatment, though complete, is very condensed; and but few simple problems and applications are provided to show the use of the subject when the analysis is established.

The author never employs the hyperbolic functions, although their use can be traced back to Newton ("Principia," Lib. II., Prop. ix.); but in the reductions of the integral of $F(x, \sqrt{R})$ where R is the quadratic $a+2bx+cx^2$, the use of $\sqrt{R}$ as the argument in conjunction with the circular and hyperbolic functions enables us to present the different results which arise in a more systematic manner than that employed in the present work. A very short sketch is also given of the method of reduction of the integrals when R is of the third or fourth degree; the elliptic integrals are now introduced, but no mention is made of the elliptic *functions*, introduced by Abel by the inversion of the elliptic *integrals*.

The Fourth Book, which treats of the integrals of complex functions and of the general properties of analytic functions, is probably the sole presentation of this modern and difficult subject in our language. To a mathematician of Mr. Cathcart's development the treatment will appear very concise and elegant, but for our part we miss the footholds afforded by the physical applications of the general theorems of functions; say to Hydrodynamics, such as those recently published by Prof. W. Burnside in the Proceedings of the London Mathematical Society, on Riemann's Theory and on Automorphic Functions, determined from their discontinuities.

The book will recommend itself, as we said at the outset, to the advanced student, who pursues mathematical study as an end to itself, by reason of the strict logical order in which the subjects are presented; but is this strict logical order the most suitable arrangement for a beginner?

Herbert Spencer says that "in each branch of instruction we should proceed from the empirical to the rational." In the operatic version of "Manon" the events are presented in chronological order; but in the original "Histoire de Manon Lescaut" the story begins in the middle, so as to excite the reader's curiosity as to the preceding events which led up to the point at which the characters appear on the scene.

According to Prof. Harnack's preface, the present work may be considered the operatic version of his lectures, while the simple story would appear in the lectures delivered in the Dresden Polytechnicum to his technical students, who required a knowledge of Analysis chiefly as an instrument for the solution of mechanical problems.

Mr. Cathcart explains in his Translator's Note the desire he had to make these lectures accessible to the English reader, and records the regret he felt at the news of the death of Prof. Harnack, while engaged on a revision of his notes for a new edition. The thanks of the mathematical world are due to Mr. Cathcart for the care and trouble he has taken in this valuable piece of work.

A. G. GREENHILL.

ALTERATIONS OF PERSONALITY.

Les Altérations de la Personnalité. Par Alfred Binet. Bibliothèque Scientifique Internationale. (Paris: Ancienne Librairie Germer Baillière et Cie., 1892.)

IN what is in ordinary parlance called somnambulism, or sleep-walking, the patient rises in the night, performs a number of seemingly intelligent actions directed to some special end, answers questions with regard to such actions with a variable amount of coherence, returns to bed, and generally, but not in all cases, wakes in the morning with no remembrance of that which he has done during the night. Such is somnambulism in its narrower sense. It exhibits the individual in an abnormal psychological condition, the actions performed in this abnormal condition being generally unconnected in memory with the normal sequence of events in waking life. The word somnambulism is, however, now used in a wider and at the same time more technical sense, being applied to all cases where the individual, either spontaneously or through hypnotic suggestion, falls into an abnormal condition distinguishable from the normal condition of his or her waking life. It is with the alterations of personality exhibited during the state of somnambulism in this wider sense that M. Binet's volume chiefly deals.

The subject is one that is beset with peculiar difficulties, and one in which extreme caution is necessary in drawing anything like definite conclusions. But it is one that is throwing, and is likely to throw, important side light on normal psychology, and one that may prove helpful in elucidating the difficult problem of the nature of the association of brain and consciousness. It will only be possible in the space at our disposal to indicate the nature of some of the evidence M. Binet adduces, and the interpretation suggested by this learned and lucid writer.

The phenomena of so-called spontaneous somnambulism are somewhat as follows. The patient is, we will say, a dull and melancholy young woman. She falls into a deep and prolonged sleep, or suffers from an hysterical or convulsive crisis. On waking from the sleep, or emerging from the crisis, she is in an altered condition, with little or no memory of her previous life, and no apparent knowledge of her friends and relations. Her character is changed: no longer dull and melancholy, she is bright and merry. In this state she remains for a time, learning anew the ways of the world, and daily profiting by her fresh experiences. Then she falls again into deep slumber, or other crisis, from which she emerges her old self once more, taking up her normal dull and melancholy life just where she left it. She remembers nothing that happened in her abnormal or second state. There is no continuity between the two. Such alterations of personality may continue at varying intervals for many years.

Somewhat similar are the phenomena observed in the somnambulism induced through hypnotic suggestion. M. Janet's subject, Léonie, is a serious and rather sad person, calm and slow, very mild with everyone, and extremely timid. Hypnotized, she becomes a different being. She keeps her eyes closed, but her other senses are abnormally acute. She is gay, noisy, and restless; good-natured, but with a tendency to irony and sharp jesting. In this condition she repudiates her former self. "That good woman is not myself," she says, "she is too stupid!"

M. Binet, summarizing the principal modifications of memory in hypnotic somnambulism, says that the subject, during the normal condition, remembers nothing of the events which have taken place during somnambulism, but that, when hypnotized, he may remember not only the occurrences in former somnambulisms, but also those which belong to the normal state. There is thus some continuity of the normal into the hypnotic personality, but none from the hypnotic to the normal. "Le livre de la vie somnambulique se ferme au réveil, et la personne normale ne peut pas le lire."

But though there is no conscious memory in the waking state of what has occurred during somnambulism, it is said to be possible to unseal the register thereof through automatic writing. A fact is told to the subject in the state of somnambulism under hypnosis, and the subject is then restored to the normal state. He has no recollection of the fact, and knows nothing about it. But slip a pencil between his fingers, hiding the hand from his eyes by means of a screen, and he will write down the fact automatically (Gurney).

In cases of so-called "negative hallucination", or "systematic anæsthesia," the subject under hypnotic suggestion neglects and is apparently blind to certain objects. For example, two out of a number of blank cards are marked with a cross, and the subject is made blind to these. If she be given a dozen cards, and among them these two, and if she be asked to count the cards, she will neglect these two and reply that there are ten. But if a pencil be slipped between her fingers, and she be asked in a low voice how many cards there are, she will reply, in automatic writing, *two*. And if she be asked, in the same tone, why she said ten and neglected these two, she will write in reply that "she could not see them."

On the basis of such observations as are here briefly summarized, and others for a description of which we must refer our readers to the book itself, M. Binet contends that, associated with the same physical individual, there may be two (or more) personalities, both of which are conscious. They may be co-existent or successive. Anæsthesia is the barrier which separates co-existent personalities: amnesia the barrier which separates successive personalities. "En un mot, il peut y avoir chez un même individu, pluralité de mémoires, pluralité de consciences, pluralité de personnalités; et chacune de ces mémoires, de ces consciences, de ces personnalités ne connaît que ce qui se passe sur son territoire." We do not propose to discuss this position. Suffice it to say, that for ourselves we see no satisfactory evidence of the *co-existence* of two personalities *both of which are simultaneously conscious*. Strange alterations and modifications of personality may occur under peculiar circumstances; but this is something very different from the supposed co-existence of two or more distinct consciousnesses.

C. Ll. M.

OUR BOOK SHELF.

Volcanoes: Past and Present. By Edward Hull, M.A., LL.D., F.R.S. With Forty-one Illustrations and Four Plates of Rock-sections. (London: Walter Scott, 1892.)

In this new volume of the "Contemporary Science Series," Prof. Hull has given a very readable account of the phenomena of volcanoes and earthquakes. A short introduction to the subject of vulcanology is followed by a sketch of the active and extinct volcanoes of Europe, and this by an account of some of the "dormant or moribund volcanoes of other parts of the world." From this description of recent volcanoes, the author proceeds to the consideration of the Tertiary volcanic districts of the British Islands, and the pre-Tertiary volcanic rocks of our own and other countries. The two concluding chapters of the book are devoted to a consideration of the remarkable eruption of Krakatão in 1883, and the great earthquakes which during the last few years have attracted so much attention, with a discussion of some of the volcanic and seismic problems suggested to the author by his review of the phenomena. These problems are classed by the author under the following heads:—"The Ultimate Cause of Volcanic Action," "Lunar Volcanoes," and the question: "Are we living in an Epoch of special Volcanic Activity?" An appendix gives "A Brief Account of the Principal Varieties of Volcanic Rocks."

In a little book of 270 pages it has of course been impossible for the author to do full justice to such a wide circle of topics, and it is sometimes difficult to detect the principle on which certain subjects have been included, and others rejected by him. But the author may be fairly credited with having accomplished his main object, which he has defined as follows: "To illustrate the most recent conclusions regarding the phenomena and origin of volcanic action by the selection of examples drawn from districts where these phenomena have been most carefully observed and recorded under the light of modern geological science."

An admirable feature of the work is the recognition of the principle that vulcanological problems may often be better attacked by the study of ancient and greatly denuded volcanoes, rather than by the examination of those in actual activity, or of such as have recently become extinct.

"*Encyclopédie scientifique des Aide-mémoire*":—
Résistance des matériaux. Par M. Duquesnay.
Étude expérimentale calorimétrique de la machine à vapeur. Par V. Dwelshauvers-Dery.
Air comprimé ou raréfié. Par Al. Gouilly.
(Paris: Gauthier-Villars, Georges Masson.)

THESE three little hand-books on their respective subjects are made by the separate publication of the respective articles of the "Encyclopédie scientifique"; it is intended that each subject is to appear in a separate volume at a rate of publication of thirty to forty a year.

There is no indication by numbering as to the order of appearance, so that probably these are the pioneer volumes.

The first volume, "La résistance des matériaux," gives a very clear and concise account of the practical side of Elasticity, so far as required by the engineer in the design of beams, columns, bridges, and retaining walls.

Prof. Dwelshauvers-Dery is well known for his theoretical and experimental researches on the Steam Engine, and his treatise may be considered as the application of the empirical laws of saturated vapours to the theoretical determination of the useful effect obtainable in the different forms of steam engine, simple or compound, with an attempt at the evaluation of the loss due to conduction. The results arrived at are checked by comparison with long-continued steam-engine trials carried out by Hirn, Donkin, Longridge, and the author himself.

The third volume, on "Air comprimé," may be supposed to carry out the same development of abstract Thermodynamics when the medium is supposed to behave as a perfect gas. In this case the mathematical laws, developed at the outset, are capable of more ready and immediate application; and the second half of the book gives a detailed account of the employment of air as the medium for the transmission of energy in its various industrial applications—for instance, as laid on in Paris compressed in mains, or as employed when rarefied in the Westinghouse brake.

A useful feature in these books is a page at the outset, in which the notation to be subsequently employed is carefully explained.

The Mechanical Equivalent of Heat is taken as 425 kilogrammetres, presumably at Paris; the mean of Prof. Rowland's experiments gives about 427 Baltimore kilogrammetres, or in absolute measure about 42 million ergs, or 4·2 joules.

The "Encyclopédie" is to be divided in interest between the *section de l'Ingénieur* and the *section du Biologiste;* the volumes promised in the first section, as in course of preparation, will constitute a valuable technical working library. G.

Chambers's Encyclopædia. New Edition. Vol. IX. (London and Edinburgh: W. and R. Chambers, 1892.)

THE new edition of this admirable Encyclopædia is now approaching completion, and in the present volume there is certainly no falling-off in the ability with which the work has hitherto been written and edited. On all important subjects represented by words between "Round" and "Swansea" there are articles summing up the latest results of research. An excellent article on round towers, by Dr. Joseph Anderson, is given on the first and second pages. This is a model of what such a paper ought to be. The author knows his subject thoroughly, and consequently understands where to draw the line between ascertained facts and the theories based upon them. Another well-arranged archæological contribution by Dr. Anderson is the paper on sculptured stones. Dr. John Murray writes with his usual lucidity on the sea and on sounding. The task of expounding the facts and laws relating to sound and to the spectrum has been intrusted to Prof. Knott, and the Rev. E. B. Kirk contributes the articles on the sun and the stars. Dr. Buchan is the author of a clear and interesting paper on storms. Other scientific articles which may be specially noted are those on the Silurian system, by Prof. James Geikie; on the skull, by Dr. D. Hepburn; on the snail and the slug, by Mr. T. D. A. Cockerell; on snakes and spiders, by Mr. J. A. Thomson; on the steam-engine, by Prof. A. B. W. Kennedy; and on the steam-hammer, by Prof. T. H. Beare. Among the geographical contributions are articles on Russia, by Prince Kropotkin; on Siam, by Mr. J. S. Black; on South Australia, by Mr. J. Bonwick; and on Spain, by the Rev. Wentworth Webster.

A Guide to Electric Lighting. By S. R. Bottone. (Whittaker and Co., London, 1892).

IN this work the author gives a general idea of the various methods of electric lighting, without entering into any of those technicalities which tend to confuse rather than enlighten the ordinary reader. Commencing with descriptions of the various batteries that are now employed, he discusses their particular advantages and disadvantages, adding also a table of their E.M.F., currents, and resistances.

The second chapter, which is devoted to the production of currents by means of the dynamo, will enable the reader to form some idea as to the selection of one of these machines for a given purpose, and to understand its general principles. Perhaps the chapter on electric lamps and accumulators will be found the most serviceable, for one is brought far more into contact with them than with dynamos themselves. The information here will enable anyone to set up a small installation for himself, while a very useful table shows the dimensions, capacities, weights, &c., of accumulators suitable for such work.

The remaining chapters deal with the descriptions of some of the smaller appliances necessary in connecting up the supplier of electricity, whether it be dynamo or accumulator, with motors or transformers, and last but not least with an excellent *résumé* of the cost of maintenance, showing the relative prices of gas and electricity as now regulated.

The book contains numerous illustrations, and as a thoroughly practical and handy work should be widely read.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"The Grammar of Science."

TO the vast majority of readers, chapter ix. of the "Grammar of Science" will probably seem to be simply a plea in favour of the doctrine of evolution in its purest form. We were not called upon to express any opinion as to the merits of this doctrine, nor did we. What struck us (and still strikes us) as fundamentally illogical, was the formulation of a theory, which, itself avowedly a mental product, proceeded to picture a universe devoid of sentient beings, or, in the phraseology of the "Grammar," a conceptual world evolving the perceptive faculty which creates it. An evolution theory which postulates spontaneous generation and human automatonism is natural to the materialist; and hence our contention that, in spite of the general character of the argument in the earlier chapters of the book, certain conclusions are distinctly materialistic.

Again, we are not of those who would bind down all time to Newton's views on matter, force, and motion. That never has been the position of those whom Prof. Pearson delights in nicknaming the Edinburgh school. Only we think a writer should be careful as to what he imputes to Newton. Thomson and Tait say, "We cannot do better, at all events in commencing, than follow Newton somewhat closely": and unless they have misrepresented the teaching of the "Principia," an attack on their version surely amounts to an attack on Newton. Indeed, Prof. Pearson fully realizes this himself, when, on p. 382, he accuses Newton of thinking of "force in the sense of mediæval metaphysics as a cause of change in motion." It was this statement we took exception to. Similarly, we cannot but look upon Prof. Pearson's obvious jeer at Maxwell's language as of the same gratuitous character.
